- Women with certain risk factors may need more frequent screening, including those who have HIV, are immunosuppressed, were exposed to diethylstilbestrol (DES) *in utero*, and have been treated for CIN 2 or 3, or cervical cancer.

Serology has been used as a marker of infection, but its clinical relevance is limited. The appearance of antibody lags behind the detection of papillomavirus DNA, typically taking 6–12 months to develop, so the antibody response might only be detected after clearance of the virus. Many people with persistent infection do not have detectable antibodies, but this could be due to poor assay sensitivity. How long serological markers can persist is not well-documented. Serology has little value in the diagnosis because of its low sensitivity and specificity. One serological parameter that may be useful for following the course of HPV disease is seroreactivity to the E6 and E7 portions of oncogenic HPV types that are capable of transforming cells in culture. Dereglulation of these genes appears to play a key role in the malignant conversion of cervical cancer precursor cells.

Various methods used for DNA detection include Southern blot, Dot blot, *in situ* hybridization, and polymerase chain reaction. Southern blot hybridization is considered as the “gold

standard” for the detection of HPV DNA because of its high sensitivity and specificity; however, it is too cumbersome and slow for routine use.<sup>23</sup> It is implied only for research purposes and for quality control.

## Vaccines

There are currently two prophylactic virus-like particle (VLP) vaccines available, Gardasil (Sanofi-Pasteur MSD), a quadrivalent vaccine containing VLPs for 6, 11, 16, and 18; and Cervarix (GSK), a bivalent vaccine containing the VLPs for 16 and 18. In 1999, it was reported that the L1 capsid protein naturally refolded into a three-dimensional conformational structure, was for all intents and purposes, a perfect copy of the exterior of the natural virus particle.<sup>33</sup> This seminal discovery allowed the subsequent development of VLP vaccines. Passive transfer of serum into naïve animals from previously VLP-vaccinated animals showed that animals could be completely protected from infection with live virus.

The outstanding feature of these 2 vaccines has been the almost 100% protection from clinical disease such as high-grade CIN 2/3, which are accepted as the precursor lesions of malignant transformation. Furthermore, it has been shown that the quadrivalent vaccine is fully protective against clinical disease from genital warts caused by types 6 and 11. The protection against clinical end-points of disease has been shown to extend until the present day (at time of printing). Both vaccines will protect against approximately 70% of cervical cancer cases. Women already infected with the subtypes contained in the vaccines will not have this protection and will still be at risk of infection from non-vaccine subtypes in the future.<sup>34</sup> The vaccines have been shown to provide a degree of cross protection against subtypes not included in the vaccines such as types 45 and 31.<sup>35</sup>

The mode of action of these vaccines is thought to be the induction and production of anti-L1 antibodies. The VLPs are potent immunogens (enhanced by adjuvant in the vaccines) and given via the intramuscular route, which ensures rapid dissemination of the antigens to the lymph nodes. This results in high levels of neutralizing antibodies, which are able to bind to virus and prevent entry and infection of cells. These levels of antibodies are usually 2–3 logs higher than that seen in natural infection with the virus.<sup>36</sup> There is poor correlation between antibody levels and efficacy, and those with very low or even undetectable antibody levels might have protective immunity. HPV almost certainly requires breaks in the epithelium down to the level of the basement membrane to establish an infection. When such breaks occur they are rapidly filled with serum containing neutralizing antibody. HPV antibody appears to be able to prevent such infections at very low concentrations. Mathematical modeling of the duration of antibody responses based on current knowledge of virology, vaccinology and immunology predicts that benefit of vaccination is likely to be life-long, with a reduction of natural diseases in 76%.<sup>37</sup>

The current vaccines are expected to confer a degree of protection against all HPV-related cancers, such as other

anogenital cancers (i.e., anal, vulval, vaginal, penile, etc) and subsets of head and neck cancers, in which the dominant subtypes are HPV 16 and 18. The quadrivalent vaccine will additionally protect against the development of genital warts and recurrent respiratory papillomatosis. Most countries which have been able to afford the vaccine have so far opted to vaccinate only young women, which has had the impact of reducing disease in young men also. Ideally, young men, especially men who have sex with men, who will not benefit from this type of vaccination strategy, but who carry a significant risk of infection, should also be vaccinated. Although health strategists might not consider this to be “cost effective” in terms of money saved, men could be protected against both warts and HPV-related cancers, and their vaccination would also benefit herd immunity.

Recent data from Melbourne, Australia, where the quadrivalent vaccine was introduced for young women in April 2007, has shown a halving in diagnoses of genital warts in women under 28 years of age, and a 17% reduction in diagnoses in heterosexual men.<sup>38</sup>

Although the vaccines are prophylactic and therefore need to be targeted pre-sexual debut to prevent infection, there is evidence that there is clinical benefit for the vaccination of young women who are already sexually active.<sup>39</sup> A young woman already infected with one subtype should derive protection from the remaining subtypes in the vaccines. Currently there are attempts to produce the next generation of prophylactic vaccines based on the L2 protein, which it is hoped might produce near “universal” coverage of subtypes.<sup>36</sup>

## Conclusion

There have been considerable advances in recent years in the understanding of the natural history of HPV infection, and much of this has been a consequence of the vaccine development program. There remain many unanswered questions such as the exact nature of the complex virus-host interaction which confers viral oncogenicity, the understanding of which might lead to new cancer treatments; how long HPV might remain latent and inactive within the epithelium, and whether this matters clinically; whether different types of HPV might have a synergistic role in the development of cancer; and what types of HPV are truly oncogenic in different clinical contexts? As we move forward into a world in which more and more people are vaccinated against a small number of viral types, the need to answer to questions such as these will become increasingly necessary.

# Anogenital Warts, Intraepithelial Neoplasia, and their Clinical Management

Paul Fox • David Rowen

# 30

## Introduction

Anogenital warts have been recognized as a disease entity for many centuries. They were certainly recognized by early Greek and Roman physicians, such as Hippocrates and Galen. The term condyloma is derived from ancient Greek, meaning “a round swelling adjacent to the anus.” The addition of the suffix *acuminata* is a relatively new feature, appearing towards the end of the 19th century. The perception that anal warts were a manifestation of a homosexual lifestyle is evident from writings of the first century; writings from the sixth century suggest that cautery was used as a treatment and that surgeons had little sympathy for their patients with anal warts.<sup>1</sup> The spectrum of HPV related disease is protean.

## Clinical Features

Anogenital warts are often multifocal. The most common sites, in the uncircumcised male, are the glans, the inner aspect of the prepuce (Fig. 30.1) and the frenulum.<sup>2</sup> In circumcised males, the shaft is also commonly affected. In females, warts are found commonly affecting the labia minora and majora, introitus (Fig. 30.2), the posterior fourchette extending onto the perineum, and in the perianal region.<sup>3</sup> These locations in both men and women tend to be the sites most prone to microtrauma during sexual intercourse, which facilitates viral access to the basal layer.

In men the urinary meatus is affected in up to 25% of cases, whereas in women, this site is affected only in 4–8%. Warts occur less commonly inside the vagina and can sometimes be detected on the cervix on speculum examination (Fig. 30.3). The morphology and pigmentation of warts is, in part, determined by their anatomical location. Pigmented warts (Fig. 30.4) are not uncommon in hairy areas including the labia majora, penile shaft and perianal area, and pigmentation at these sites should not cause alarm.

Warts may be broadly divided into three major morphological groups: acuminate warts, which are found on mucosal surfaces and are characterized by being formed around vascular, finger-like

projections (Fig. 30.5). They usually have an irregular surface, which may give the appearance of fissuring. Individual lesions may coalesce to form larger lesions, which are not infrequently seen in pregnancy and in immunodeficient states. Bleeding can occur following minor trauma because of the vascularity and this may be the presenting complaint.

Another type is the flat or macular wart, which can be difficult to distinguish from low grade intraepithelial neoplasia (*vide infra*) and other skin conditions. A traditional way of distinguishing HPV related lesions from other lesions is to cover then with a piece of gauze soaked in 5% acetic acid for 5 minutes. Warts

**Fig. 30.1:** Warts on the inner surface of prepuce.

**Fig. 30.2:** Warts in the vagina.

**Fig. 30.3:** Wart on the cervix.

**Fig. 30.4:** Pigmented papular warts.

and intraepithelial neoplasia will become white, the so-called acetowhite, but the specificity of the procedure is low because inflammatory lesions can also be highlighted.<sup>3</sup>

The third morphological wart type is thick, papular, highly keratinized variety which tends to occur in extramucosal locations on stratified squamous epithelium, analogous with common warts.

A rare variant is the so-called Buschke–Löwenstein giant tumor (Fig. 30.6). This HPV-6 and 11-associated lesion is characterized by downward growth into dermal structures. Although locally invasive, it does not metastasize, except in immunocompromised patients such as those with HIV infection, in whom there is a risk of transformation into squamous cell carcinoma.<sup>4</sup> Histologically

the lesion forms a complex pattern of acanthosis, koilocytic changes as well as foci of markedly atypical squamous cells.

The psychological impact of developing anogenital warts should not be underestimated. Many patients will be distressed, experience relationship difficulties due to concern about infidelity of their partner, and express feelings of low self-esteem.<sup>5</sup> Some patients, especially women, will be concerned with regard to malignant transformation of anogenital warts and whether the warts will affect fertility.

The complications of genital HPV during pregnancy include rapidly enlarging and spreading warts and obstruction of the birth canal when large condylomatous lesions fill the vaginal outlet. Neonatal laryngeal or respiratory papillomatosis can occur when HPV is vertically transmitted from mother to the newborn during vaginal delivery.

## Differential Diagnosis

The differential diagnosis of genital warts include pearly penile papules, vulvar papillomatosis, skin tags, molluscum contagiosum, seborrheic keratosis, bowenoid papulosis, and squamous cell carcinoma of penis or vulva.<sup>6</sup>

Recurrent respiratory papillomatosis is rare, affecting only 4 per 100,000 live births, but is extremely distressing and expensive to manage.<sup>7</sup> In order to prevent this, some clinicians advise women with clinically evident genital warts to have delivery by caesarian section, but this is far from common practice.<sup>8</sup> There have been rare instances of children being affected despite caesarean section, presumably as a result of transplacental infection.<sup>9</sup> The papillomas typically occur in the upper respiratory tract, especially the soft palate, epiglottis, and the bronchial spurs, but ciliated epithelium anywhere within the respiratory tract can potentially be infected. Respiratory obstruction can supervene, and regular surgical clearance is often necessary. Malignant transformation occurs in 3–7% of cases typically in association with HPV-11. The condition can also develop in adulthood, presumed usually to be a rare consequence of sexual transmission, but it has also been known to affect surgeons performing electrosurgery on warts with inadequate smoke extraction.

## Management

The aims of treatment should be carefully explained to patients, as also the reason for treating the warts.<sup>10</sup> The major reason for treatment is for cosmetic purposes. Treatment may also reduce infectivity, although there is no overwhelming evidence to support this contention. It should be noted that HPV-6 and 11, the usual cause of anogenital warts, have little oncogenic potential and patients can be reassured accordingly. Patients should also be advised concerning latency of papillomavirus; the partner from whom they acquired the virus may not be their current one. Patients presenting with warts should routinely be screened for other sexually transmissible infections.<sup>11</sup> Patients with warts at the anal margin should have the anal canal visualized using a proctoscope, as a high proportion will have additional warts at this site. This might reasonably be deferred until the external warts have been cleared, unless the patient has intra-anal discomfort suggestive of the presence of warts. There is always a possibility that clearance of external warts might lead to spontaneous resolution of the internal warts through the development of effective immunity. Patients with perianal warts are frequently concerned that they may be thought to have engaged in receptive anal sexual intercourse. Although such warts may result from virus transmitted by this means, it is much more likely that perianal infection results from spread of infection from adjacent sites. Warts at the anal margin can sometimes be a consequence of scratching in a patient with perianal warts, but for true intra-anal warts there is a strong association with receptive anal intercourse.

The treatment of anogenital warts is determined by the size, and anatomical site of the warts, whether the warts are keratinized or fleshy. No specific treatment is appropriate for all patients. One

should always consider the option of not treating the warts, as it has been reported that spontaneous resolution of warts may take place. Coleman et al. reporting a 50% spontaneous regression in wart size in a fifth of patients over a 4-week period.<sup>12</sup> Controlled treatment studies have invariably shown that a significant portion of warts will also be cleared in the placebo arm. Warts may grow rapidly in pregnancy, but can regress with similar rapidity following delivery. The majority of the treatment modalities aim at wart clearance, the underlying HPV infection is not addressed. Hence, recurrence following apparently successful treatment is not uncommon. Reported recurrence rates range from 0–91%, dependent on treatment modality.<sup>13</sup> All treatment modalities will, to some extent, cause local skin reactions, e.g., erythema, ulceration, and localized soreness, and patients should be advised accordingly.

## PODOPHYLLIN

Kaplan first described the use of podophyllin in 1942.<sup>14</sup> The source of the drug is the root of *podophyllum emodii* or *peltatum*. The crude extract is usually suspended in compound tincture of benzoin or in alcohol. It can also be mixed with white soft paraffin and be used as an ointment. The active ingredient in this crude extract is podophyllotoxin. Unfortunately, the amount of active material in any extract varies considerably from batch to batch, as does the amount of lignans such as quercetin.<sup>15</sup> It is these lignans which are responsible for most of the side effects of the drug. The suspension has a relatively short shelf life, although probably stable up to 3 months without undue loss of potency. A commonly followed regimen is the application of podophyllin, 25% in tincture benzoin, once or twice weekly, the suspension being washed off after 4–6 hours. Several studies have shown that more dilute podophyllin in an alcoholic vehicle, applied more frequently, is as effective as 25% podophyllin or commercially available podophyllotoxin. Highly keratinized warts do not appear to respond well to treatment with this drug, although no randomized, controlled trials have been carried out to prove this. The most common side effect of the drug is localized soreness and ulceration. Washing the podophyllin off, 4–6 hours after application, may minimize the risk of this. Podophyllin contains neurotoxins, which can cause nerve damage, and there have been rare instances of coma and death. This is seen only when a considerable amount of the drug has been absorbed through the mucosa, but patients should never self apply this treatment and it should not be applied to large areas. The drug is also potentially mutagenic and therefore should not be used in pregnancy due to the theoretical risk of teratogenicity.

## PODOPHYLLOTOXIN

The active agent of podophyllin has been purified and is available commercially both in a liquid form and as a cream. It is considerably more expensive than podophyllin, but is suitable for home treatment, therefore negating the necessity for the patient to attend clinics for treatment. It contains no neurotoxins and is an extremely safe treatment except in pregnancy because of the

potential risk of teratogenicity. Side effects of the drug are less commonly observed than with podophyllin. It is applied twice daily for 3 days each week either as a lotion or a cream, more frequent application being associated with increased frequency and severity of side effects. Several studies have demonstrated superiority over podophyllin suspension for the clearing of warts.<sup>16</sup> Apart from its low cost, podophyllin has no advantage over podophyllotoxin. Once cost benefit versus risk ratio is considered, it becomes clear that self treatment with podophyllotoxin is more efficacious than podophyllin.<sup>17</sup> Meta-analysis of podophyllotoxin studies has shown that it produces a complete clearance after 4 weeks in 49% of patients, and an overall sustained clearance at 12 weeks in 35%.<sup>18</sup>

### MONOCHLOROACETIC AND TRICHLOROACETIC ACID

The use of caustic agents such as mono- or trichloroacetic acid is of value, especially in the treatment of flat warts. Great care is required when applying to prevent burning the adjacent normal skin. Absence of systemic toxicity means that both agents can safely be used in pregnancy. Their use at the meatus is best avoided, to prevent meatal stenosis. The acid can be applied by touching the warts with an orange stick that has been dipped in the acid. Application with a swab is potentially dangerous as the amount of acid may be excessive and damage to adjacent skin is a possibility. The treated area rapidly goes white due to precipitation of protein within the wart. Patients often experience a warm sensation soon after the application. Frank discomfort is uncommon unless excessive amount of acid has been applied. Ideally the warts should be treated at weekly intervals.

### CRYOTHERAPY

The value of cryotherapy as a treatment modality is its versatility. It can be used on all types of warts, is not restricted to use at specific anatomical sites, and is safe in pregnancy. Some immediate discomfort at the site of treatment may limit its use in those with a low pain threshold. Topical local anesthetics can be applied, although these are usually considered to be unnecessary. When the cost of clinical time is factored, cryotherapy shares with mono- and trichloroacetic acid in being the least cost effective treatments because weekly treatments are required.<sup>19</sup> Furthermore, the cost of the equipment can be prohibitive in resource poor settings. The liquid nitrogen can be applied in two ways: either with a liquid nitrogen spray, or by dipping a Dacron swab into liquid nitrogen and applying this to the wart. The minimum duration of application should be that required to produce a frozen halo around the wart. The longer that the freezing is sustained the higher the likelihood of clearance, but freezing for prolonged period involves the risk of significant pain and blistering. One way of freezing for longer periods while reducing the pain experienced is to use a double freeze-thaw cycle. Another way when using the nitrogen jet is to use an interrupted jet with only enough freezing to maintain the frozen halo. In this way the tissue can be held frozen for up to 30 seconds with minimal discomfort. Cryoprobes, using either carbon dioxide or nitrous

oxide as the cryogen, are also effective; however, the equipment required can be costly. There have been concerns with regard to accumulation of nitrous oxide in the immediate environment especially when ventilation is inadequate.<sup>20</sup> There are at least three phases involved in cryodestruction, namely: the physical, vascular, and immunological. It is probably the immunological phase that is responsible for the lower recurrence rate observed following treatment with cryotherapy than with some other modalities.

### 5-FLUOROURACIL

This anti-metabolite has in the past been used topically for the treatment of warts. Side effects, namely irritation and ulceration limit its use. Furthermore, it cannot be used in pregnancy. Few trials have examined the efficacy of this substance. Guidelines do not recommend its use for the treatment of genital warts. However, a Cochrane review concluded that, 5-FU was superior both to placebo and podophyllin when the outcome considered was cure alone.<sup>21</sup>

### IMIQIMOD

This modality has a different mode of action to other wart treatments.<sup>22</sup> It is an immune response modulator which takes an average of 9 weeks to clear the warts.<sup>23</sup> The main action of imiquimod is on toll like receptors (TLR-7 and TLR-8). This activates nuclear factor kappa B (NF- $\kappa$ B) which in turn induces transcription of genes for cytokines, interferons (IFN- $\alpha$ ), tumor necrosis factor (TNF- $\alpha$ ), interleukins (IL)-2,6,8, and 12, granulocyte colony stimulating factor and granulocyte macrophage colony stimulating factor. In addition, it also releases chemokines and other inflammatory mediators. As a result of this, there is activation of cytokine producing dendritic cells and antigen presenting Langerhans cells.<sup>24</sup>

It is more effective when applied within skin folds, i.e., underneath the foreskin, in the vulva and perianally, presumably because the occlusive effect aids absorption. It is therefore most effective in women, with an end of treatment clearance of 72%. In trials where a high proportion of men were circumcised clearance falls to 37%, while in a study looking only at uncircumcised men clearance was 62%.<sup>19,25</sup> A study in which male patients were randomized to treatment with either imiquimod or cryotherapy showed that cryotherapy was slightly less effective after 3 months of treatment, and that the recurrence rate was less with imiquimod.<sup>26</sup> A meta-analysis has shown that daily application of imiquimod has no benefits over 3 times a week application. Therefore the current recommendation on frequency of application is 3 times a week.<sup>27</sup>

If there has been a partial response to the first 12 weeks of treatment, a further course will produce clearance in 27%, and for patients who developed recurrence the clearance rate was 58.5% on reapplication.<sup>28</sup> Recurrence rates are around 22% in the 3 months following effective treatment, but if treatment has previously been effective it will usually be effective when used again, and often in a shorter time frame. Patients should be warned to expect irritation and erythema at the site of application and sometimes in areas

infected with HPV where no cream has been applied. This is a common cause for discontinuing treatment, and it is helpful to give patients permission to discontinue therapy while soreness is present, and thereafter the dosage and frequency might need to be reduced. The drug is costly compared with other drugs if three boxes of imiquimod are used over a 12-week period, but if each sachet is made to last a week so that only one box is used, then it becomes perhaps the most cost effective treatment, especially for women and uncircumcised men. There has recently been some concern on theoretical grounds that treatment of warts may facilitate the transmission of HIV to susceptible patients.<sup>29</sup> This hypothesis is however not widely accepted. Imiquimod has been frequently associated with local and systemic adverse events, even induction of non dermatologic disorders. Rarely, erythema multiforme has been attributed to imiquimod.<sup>30</sup> A potential side effect of imiquimod is depigmentation of the skin following effective cure. This looks similar to vitiligo, which has also been observed to develop in the zone of application during treatment.

### SURGICAL EXCISION AND LASER

There are a number of different surgical treatment options including scissor excision, electrosurgery/hyfrecaction, and laser. These procedures can often be undertaken under local anesthetic unless the warts are very extensive or in a difficult location such as intravaginal or intra-anal, when a general anesthetic will be required. Data on comparative efficacy compared to other treatments are extremely scanty. The results of the few trials that have been published indicate that recurrence rates following scissor excision are lower than in patients treated with podophyllin.<sup>31</sup> This information is not all that useful in view of the fact that podophyllin has been established as the least effective of all the treatments for warts. Certain types of warts such as pedunculated warts lend themselves extremely well to the surgical approach, but this aside, surgery is generally considered to be a treatment of last resort after the failure of other treatment modalities because it is time consuming, painful, and can lead to considerable post operative morbidity. Among anal condylomata acuminata, HPV-11 was found to be associated with higher recurrence rates after surgical excision than other HPV types.<sup>32</sup>

An auto-implantation technique has been described.<sup>33</sup> Recurrence of warts following use of this technique was

significantly lower than in a comparable group treated with podophyllin. CMI responses were measured and these appear to be enhanced by this technique.

Carbon dioxide laser can be used for ablation. Cao et al. found that low dose cyclophosphamide prevented recurrence of large condylomata acuminata after laser ablation. The mechanism suggested was depletion of regulatory T cells by low dose cyclophosphamide and effective immune response.<sup>34</sup>

Flashlamp-pumped pulsed dye laser emits in the yellow orange part of the visible light spectrum at 585 nm. The application of 585-nm flashlamp-pumped pulsed dye laser (FPDL) light appears to be a safe and simple treatment option for the management of genital warts. The laser beam targets dilated capillaries in genital warts. Many patients require more than one session.<sup>35</sup>

### INTERFERONS

The use of interferons both as primary treatment and as an adjunct to other therapies post clearance has yielded disappointing results.<sup>36,37</sup> They are expensive, and side effects such as flu-like symptoms are common. Their use for treatment of warts therefore cannot be justified.

### COMBINATIONS OF TREATMENT MODALITIES

The use of combined treatments, such as cryotherapy plus topical podophyllin has lately become a popular choice of therapy. A comparative treatment study has usefully compared five different treatment modalities, podophyllin, TCA, and cryotherapy, with two combined treatment approaches, TCA and podophyllin, and finally cryotherapy and podophyllin.<sup>38</sup> This showed that TCA and podophyllin have similar efficacy and were both markedly less effective than cryotherapy. Combining TCA and podophyllin gave them comparable efficacy to cryotherapy, but adding podophyllin or podophyllotoxin to cryotherapy produced no significant additional benefit.

### NEWER/EXPERIMENTAL TREATMENT MODALITIES

Intralesional immunotherapy with antigens and vaccines unrelated with HPV has been found effective in different trials. No randomized controlled trials are available and intralesional injection is painful. A summary of published studies is given in Table 30.1.

**Table 30.1:** Summary of Published Studies on Intralesional Antigen Therapy for Anogenital Warts

Authors, Year	Antigen used	Mode of application	Total no. of patients	No. of patients completely cleared
Malison and Salkin, 1981 <sup>39</sup>	BCG	Intralesional	2	0 (0%)
Böhle et al. 2001 <sup>40</sup>	BCG	Topical	10	6 (60%)
King et al. 2005 <sup>41</sup>	Mumps, candida or trichophyton	Intralesional	21	5 (23.8%)
Metawea et al. 2005 <sup>42</sup>	BCG	Topical	25	23 (92%)
Gupta et al. 2008 <sup>43</sup>	Mycobacterium w	Intralesional	10	8 (80%)
Eassa et al. 2011 <sup>44</sup>	PPD	Intralesional	40	19 (47.5%)

## GREEN TEA CATECHINS

In 2006, 15% sinecatechins ointment was approved by US-FDA for topical treatment of genital warts. The drug is derived from leaves of green tea (*Camellia sinensis*). It consists of a mixture of catechins, their derivatives, and other components of green tea.<sup>45</sup> They have antioxidative, immunostimulatory, and antiviral properties. They inhibit pathways that are activated by HPV oncogenes. Sinecatechins specifically reduce the expression of HPV gene products E6 and E7.

Sinacatechins ointment is to be applied 3 times a day, up to 250 mg per application. A randomized trial reported 57.2% clearance in drug group vs 33.7% in vehicle group ( $p < 0.001$ ), 3.7% developed new warts, 6.5% showed recurrence during 12-week follow-up period.<sup>46</sup>

There was no significant difference in local reactions between drug and vehicle group. Like imiquimod, sinecatechins are more effective in women than men.

## PHOTODYNAMIC THERAPY

Aminolevulinic acid (ALA) photodynamic therapy (PDT) has shown good results in few trials with up to 60% clearance rates.<sup>47</sup> It has been found to attract antigen presenting cells in HPV infected epidermis and resultant effector T cell response.

## WARTS IN MORE DIFFICULT TO TREAT LOCATIONS: INTRAVAGINAL AND INTRA-ANAL

Cryotherapy and TCA are very difficult to use effectively at these sites. Podophyllin should not be used, but both podophyllotoxin and imiquimod creams can be very effective if used cautiously. Less than half a sachet of imiquimod should be used because systemic absorption can occur, which may result in transient flu-like symptoms many hours later. Patients who experience such a reaction are unlikely to have further problems if the dosage is further reduced. If these treatments fail then surgery is the only option. Cervical warts are best removed colposcopically.

## Prevention

The consistent use of condoms has been demonstrated to reduce the risk of acquiring genital warts.<sup>48</sup> The use of condoms while a patient is receiving active treatment for warts, and for 3 months post treatment, is often advised as a means of preventing transmission and to prevent recurrence. This advice is without any scientific justification. One study has shown some benefit for the index case with regard to time to clearance, but no published studies have shown unequivocal benefit for partners of the index case.<sup>49</sup> If patients are in long term relationships and they have been having unprotected intercourse, it is likely that both share the same type of papillomavirus, and the use of condoms at this stage is unlikely to prevent the development of warts in partners or have impact on recurrence rates. Condom use with regular partners has not been shown to affect the outcome of other manifestations of HPV infection.<sup>50</sup>

## Penile Intraepithelial Neoplasia (PIN), Vulval Intraepithelial Neoplasia (VIN), and Anal Intraepithelial Neoplasia (AIN)

Collectively these squamous intraepithelial lesions (SIL) can be divided into three basic types: subclinical, appearing only following the application of acetic acid; resembling flat warts; and thirdly and most distinctive, giving rise to red velvety lesions which have an eroded appearance because there is no normal epithelium. Histologically, SIL can be divided into low grade or grade 1 and high grade, grade 2 or 3 on the basis of whether the atypical layer of cells is confined to the locality of the basement membrane (grade 1), occupies the full thickness of the epidermis (grade 3) or is intermediate between the two (grade 2). Virologically low and high grade are distinct, with the majority of low grade lesions being associated with nononcogenic HPV-6 and 11, and the majority of grade 3 lesions being caused by oncogenic HPV types, predominantly HPV-16 and 18.<sup>51,52</sup> In an observational cohort of women in the placebo arm of an HPV vaccine study, HPV-6 or 11 was found in 65% of women who developed VIN 1. Only 6% had HPV-16 or 18, whereas 65% of those with VIN 2/3 had HPV-16 or 18.<sup>53,54</sup> It is likely that much low grade SIL is misidentified as warts and effectively treated using the customary treatments for warts. This hardly matters because such lesions have little or no malignant potential. High grade lesions which have been static in one location for a long time might undergo malignant change. It is difficult to determine an individual's risk of malignant transformation but age, smoking, and immune status (e.g., HIV positive, on corticosteroids or other immunosuppressants) should be taken into consideration when assessing risk. HPV related squamous carcinoma is extremely rare below the age of 50 years, whereas SILs are common. Even in HIV-positive patients, the rate of malignant conversion is unlikely to exceed 4% per annum. When SIL does undergo malignant change this typically manifests itself clinically as a thickening of part of the lesion which thus becomes more papular, in contrast to the normal macular appearances. Such lesions should be completely excised as a matter of urgency.

Treatment options are similar to those for warts, including surgical removal, TCA, cryotherapy, and imiquimod. The latter treatment has been shown to be highly efficacious for VIN in a placebo controlled study.<sup>55</sup> Therapeutic vaccines are a potential future treatment option. These aim to stimulate an immune response to the oncogenic E6/E7 proteins. A variety of candidate vaccines have been produced, and one of these has so far shown efficacy in the treatment of VIN based on preliminary results, but with severe local side effects at the injection site.<sup>56</sup> Prophylactic vaccination does not induce regression of SIL, although there remains a theoretical possibility that it might have a protective benefit in preventing the development of lesions in new areas.

The anal squamocolumnar junction is structurally very similar to that on the cervix, and there are reports that heterosexuals who have never engaged in receptive anal intercourse can develop AIN at this site, although the risk is very much greater if there

is a history of receptive anal intercourse. Cohort studies using cytology have shown that at least 5% of MSM, both HIV positive and negative, have SIL across all age cohorts, but the incidence of anal cancer is very much greater in the HIV positives, showing a steep rise over the last 10 years.<sup>57</sup> A range of treatments have been used for anal canal AIN, including imiquimod, TCA, laser, infra-red coagulation, and electrofulguration. All of these methods are used in conjunction with high resolution anoscopy, a procedure very similar to colposcopy. There are high recurrence rates with all these treatments in HIV positive individuals, but there are benefits to sustained treatment. Long-term follow-up of two clinic cohorts of HIV positive patients who have undergone treatment over several years for high grade internal AIN show an overall sustained absence of high grade lesions in 61% of patients.<sup>58,59</sup> The treatment modalities used at these two centres were imiquimod, TCA, and laser. Cytological surveillance to detect AIN is starting to be used more and more in high-risk populations, so that those with high grade disease can be aware of an increased risk of cancer. Regular digital anal examination for any lumps by the patient and/or the clinician in this group is advisable to pick up anal cancer at an early stage when simple surgical excision would usually be curative.

### Summary

Given the scale of papillomavirus infection, with either high or low risk types, it is clear that there is need for strategies, both to prevent primary infection, and to deal with established infection and its sequelae. Condom use may prevent initial infection, but once infection is established the benefits of condom use are much less certain. The wide range of treatments available is a reflection of the fact that there is no ideal treatment. There is no single treatment modality that is suitable for all patients with anogenital warts. No currently available treatments, with the exception of imiquimod, target the virus. Consequently recurrences are not uncommon. All treatments, including imiquimod, have definite failure rates with regard to both clearance and recurrence. Utilization of the new quadrivalent HPV vaccine offers great hope for the future, but the current high cost precludes its use in the developing world where it is most needed, and vaccination cannot help individuals who have already acquired HPV infection.

# Molluscum Contagiosum

Jyoti K. Dhar

## Definition

Molluscum contagiosum (MC) is a benign proliferative skin condition lasting several months and commonly affecting children, sexually active adults, and immunocompromised individuals. Bateman, as early as 1817, assigned the condition its name based on the characteristic appearance and expressibility of a milky fluid. This expressed material was considered infectious (Handerson–Peterson or molluscum bodies) besides being responsible for transmission.<sup>1</sup>

The viral nature of MC was first hypothesized in 1905 by Julius Burg. In 1933, it was established that infection is caused by a double-stranded DNA virus of the pox family, a sole member of the genus Molluscipox virus, represented by MCV1 and MCV2.<sup>2</sup> The MCV is the largest of all animal viruses currently known and is easily visualized on light microscopy. Following the eradication of smallpox, it remains the only poxvirus to infect humans. Unlike smallpox, however, infection with MCV has not been clinically significant, except during the pre-HAART (highly active antiretroviral therapy) period of HIV disease when clinical presentation with MC is common, causing serious morbidity in HIV-infected individuals.

## Pathogenesis

The exact pathogenesis of MC is unclear and has not been completely elucidated. Immunity, both cellular and humoral, appears to play an important role in the resolution of established infection. Transmission occurring through direct skin contact with an infected individual is well-recognized. Viral inoculation is triggered by superficial damage to the epithelium. Abnormal epithelial cell proliferation of the basal layer with acanthosis follows, leading to the hyperplastic, folded epithelium. The presence of free virus cores, or viral factories, has been reported, mainly affecting all the layers of the epidermis, including the malpighian and granular cell layers.<sup>3</sup> A few studies have shown mononuclear infiltration occurring in the healing stage of the infection. It is postulated that the viral localization in the epidermal keratinocytes, the lack of inflammatory cell infiltrate seen in *in vivo* lesions, and the noticeable absence of T and NK

cells in molluscum lesions may partly explain the phenomenon of immune evasion (see below).

These skin lesions or “pocks,” as they are sometimes called, are small and can persist for months before resolving spontaneously.

In patients with impaired immunity, they have been noted to become larger and persist for longer periods.

Research into MCV has also been hindered by an inability to replicate the virus in tissue culture (which appears to be due to a defect in the expression of the genome) and the absence of useful animal models. Currently, there is no *in vitro* or animal model available for MCV, and while investigators have been able to infect human skin with molluscum contagiosum virus and graft it onto athymic mice, no continuing viral replication was noted.<sup>4</sup>

The MCV genome is a linear, double-stranded DNA molecule of 180–200 K bases; in length, a continuous strand of self-complementary DNA. Structural similarity of the MCV DNA to the vaccinia virus DNA implies a similar mechanism of replication. DNA restriction endonuclease digest patterns have demonstrated four genetic MCV subtypes designated as MCVI, II, III, and IV with common variability. A high degree of homology between the subtype genomes with highly conserved organization has also been observed. In contrast to the herpes simplex virus (HSV) subtypes, no proliferation association of MCV subtype with site of infection has been noted, despite earlier indication that this might be so.<sup>5</sup>

## Immune Evasion in Molluscum Contagiosum

The immune response to a viral infection is a complex phenomenon that is specific to the organism. Similarly, the MCV also encodes specific molecules to control host defenses and seems to utilize several methods to escape detection by the immune system. Studies have shown that chemokines, like growth-regulated oncogene alpha (GRO) and IL8, are found inside the molluscum lesion as they are released with the clearing of the virus.

Analysis of the MCV genome has revealed more than 70 putative genes that are not seen in other pox viruses, with an additional 100 genes.

The former include a viral homology of cellular chemokines like MCV open reading frame (ORF) with chemokine antagonist activity (mcv148R); others encode A104 amino acid protein with significant homology to a major HLA complex class 1 that binds to beta microglobulin (mc80), subsequently blocking the chemotactic activity of the host chemokines. MCV gene products such as MC53L and MC54L bind IL18 and prevent IFN-gamma production. IL8-binding protein is used as a decoy receptor by the pox virus (MC54 leads to pirating of the receptor).

Other domain proteins that inhibit TNF (MC159, MC160) have been isolated, creating products that inhibit the cellular NF-kappa B protein complex and thus preventing the production of pro-inflammatory molecules and enhancing viral survival. MC66 produces selenocysteine-containing glutathione peroxidase that inhibits peroxidase and UV-mediated apoptosis.<sup>6</sup>

Dermatotropic viruses like HSV produce similar immune evasive proteins thus explaining their persistence.

## Histology

MCV exhibits a lobular proliferation of surface epithelium, showing an aggregation of enlarged keratinocytes that are engorged with viral inclusions (molluscum bodies) usually seen in the centre of the lesion (Fig. 31.1a). The nucleus becomes compressed at the level of the granular cell layer, and the molluscum bodies lose their internal structural markings and develop a homogenous, ground glass, eosinophilic appearance that appears basophilic beyond the granular layer (Fig. 31.1b). Pseudocystic and polypoidal variants of this appearance can be seen in immunocompromised patients. Other histological dermal changes observed are lymphohistiocytic, neutrophilic, or granulomatous infiltrates; the latter mainly seen in solitary MC lesions.

Studies indicate that clinical infection with MCV is not always associated with antibody development though indirect immunofluorescence has demonstrated antibody production in about 70% of patients with visible lesions.<sup>7</sup> Polymerase chain reaction (PCR) can also help detect MCV in skin lesions.<sup>8</sup>

## Epidemiology

This is largely unknown despite the fact that the virus is directly communicable, and large outbreaks have been known to occur. Available studies are few and have focused on rates or risk factors for infection in specific population groups. Others have been defined by geographic locations, age of the subjects, or their immunological status. Providing estimates of population-based incidence rates again is difficult, MC not being a reportable disease. Furthermore, the lack of standardized serological testing, self-limiting nature of clinical infection, and reliance on clinical examination alone for diagnosis limit further detailed study.

As humans are the only reservoir of infection, world-wide distribution is common. A higher incidence of the virus has

\*c+

\*d+

**Fig. 31.1:** (a) Part of an inverted lobule of squamous epithelium showing multiple eosinophilic molluscum inclusion bodies. These extend from above the basal layer to the keratinous debris on the surface (H&E, 10×). (b) At higher magnification (H&E, 20×). Courtesy: Dr. Gerald Saldanha, Leicester Royal Infirmary, UK.

been reported in the tropics, in institutions and crowded areas, and may be related to factors such as warmth, humidity, and poor hygiene.<sup>9</sup>

MC may affect any part of the body. Close sexual contact may be responsible for genital lesions and therefore commonly seen during adolescence and early adulthood. In adults, lower abdominal, thigh, and genital lesions are more frequent than those in extra-genital locations.<sup>1</sup> Studies indicate that for transmission, whether sexual, nonsexual, or via fomites (e.g., sharing bath sponges and towels with MC-infected individuals), close contact is important.<sup>10</sup>

MC is also an important cause of infection affecting the eyelids. Historically, this has been seen exclusively in young children; however, in the recent past this presentation has been increasingly recognized in adults with AIDS. A few isolated

case reports of congenital/vertical transmission exist, though this mode of transmission is uncommon.<sup>11</sup> Autoinoculation, as a mode of transmission, is also suspected.<sup>12</sup>

MC infection typically also occurs in 2- to 5-year-olds<sup>13</sup> and is rarely seen in children below 1 year of age, though a bimodal age distribution has also been described. While the prevalence rates are not known, a study from Netherlands reports one of six Dutch children having visited the doctor for this condition.<sup>14</sup> The same study showed a cumulative incidence rate of 17% in those under 15 years of age, while adult sexually related MC was rare.

MC, when nonsexually transmitted, appears to be more prevalent in the tropics than in Europe. A recent study reported 1.2% of 10- to 12-year-olds from Aberdeen to have the infection, while in Fiji it mainly affected 2- to 3-year-olds with 4.5% of the entire village population affected. In addition, a quarter of all household contacts were affected.<sup>15</sup> Hence, in children the presence of isolated MC lesions is not indicative of sexual abuse unless there are other clues.

Recent reports suggest that rates of MC are on the rise. GUMCAD, a dataset that monitors trends in new diagnosis of STIs in the UK, indicates a 50% increase in MC incidence between 1998 and 2008. Similarly, rates of 20% in female sex workers have been reported from India.<sup>16</sup>

MC is also seen in patients with HIV infection.<sup>17</sup> This association was first reported in 1983 and estimated prevalence rate was 5–18% in the adult group.<sup>18</sup> A recent South African study describes similar rates (21%) in the pediatric HIV cohort.<sup>19</sup> At present, there is little evidence to support MC lesions (mollusca) being more common in people with atopic dermatitis.

The incubation period of MC varies between 19 and 51 days with a wide range of 7 days to 6 months. The period of communicability, while unknown, probably lasts as long as the lesions persist. It is unknown if previous infection confers any protection against subsequent exposure. However, the greater prevalence of lesions in children than adults may suggest the acquisition of subsequent host resistance.<sup>20</sup>

### Clinical Presentation

Primary lesion of MC presents as a papular eruption of several umbilicated lesions with no systemic manifestations. The single discrete lesions are dome shaped and discrete, fleshy, white, translucent, or yellow in color (Fig. 31.2). They are usually smooth, 2–20 in number, and sometimes mistaken for pustules. At presentation, the size of the papules may vary between 2 and 6 mm, depending on the stage of development of the lesion (Fig. 31.3).

### Distribution of Molluscum Contagiosum

Any area may be involved but axillae, ante cubital, popliteal fossa, and crural folds are the favored sites. Mucous membrane involvement is uncommon, though cases with involvement of the conjunctiva and mouth have been described.<sup>21</sup> An eczematous

**Fig. 31.2:** Disseminated and multiple MC lesions seen in HIV infection. *Courtesy: Dr. K. Horn, Bath, UK.*

**Fig. 31.3:** Close view of lesions showing the characteristic umbilication.

reaction may encircle lesions in approximately 10% of patients. Facial lesions as previously described have been reported with HIV infection.<sup>22</sup>

In immunocompromised states, MC may have an atypical presentation in number (>100), in size (>1 cm), in color, and with generalized dissemination.<sup>23</sup> Large sized giant mollusca (>15 cm) and penile horns have been reported.<sup>24</sup> Extensive facial involvement with enlarging lesions is commonly seen; spontaneous resolution being rare in these cases. Lesions also tend to be prolonged, resistant to treatment, and may take 4 years or more to disappear.

In patients known to have HIV infection, the presence of MC may herald advancing immunosuppression or the development of immune reconstitution inflammatory syndrome (IRIS).<sup>25</sup>

It is recommended that the appearance of MC lesions in an adult should raise suspicion and require further evaluation for an immunosuppressed state.<sup>26</sup>

### IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

This is a paradoxical clinical deterioration that is observed in HIV-positive individuals after the introduction of HAART.<sup>27</sup> It represents a diverse range of immunopathological reactions manifesting as improvement of the individual's HIV surrogate markers<sup>28</sup> and immune restoration. Approximately half of these events are dermatologic, the commonest clinical signs reported are herpes simplex infection, herpes zoster, and MC.<sup>29</sup>

### Complications

These are uncommon, though irritation and secondary infection with abscess development have been reported.<sup>30</sup> Disseminated eruptions may also be seen in patients with atopic dermatitis (steroid use, skin trauma, and immunological mechanisms are cited as contributory factors).<sup>31</sup> Occasionally, involvement of the eyelid or conjunctiva may lead to abscess formation.

### Diagnosis

Diagnosis is made on clinical examination, based on the appearance of the characteristic, umbilicated skin lesions (using a magnification lens maybe helpful in some cases).

Histological examination of a curetted or biopsied lesion can help in the diagnosis of difficult cases that are not clinically obvious.

For cytological preparations, the thick white central core can be expressed and smeared on a slide or smears can be made from scrapings of lesions. Smears left unstained or stained with Geimsa, Gram, Wright, or Papanicolaou stains will demonstrate the large brick-shaped inclusion bodies (Fig. 31.1).

Electron microscopy of fixed material from a papule has been used to demonstrate the poxvirus structures of the dumbbell-shaped viral particles.

Immunohistochemical methods using a polyclonal antibody allow recognition of MC in fixed tissue.<sup>32</sup> *In situ* hybridization for MCV DNA has also been utilized.

Laboratory tests for complement fixation, tissue culture, neutralization, and fluorescent antibody are not standardized and not routinely used for diagnosis.

If sexually acquired, MC in adults should raise the possibility of other infections and screening tests for other sexually transmitted infections should be offered.

### Differential Diagnosis

Skin conditions that need to be considered in the differential diagnosis and may coexist with MC are genital warts. Other conditions that simulate the skin lesions are keratoacanthoma, basal cell carcinoma, syringoma, lichen planus, sebaceous adenoma, naevi, histoid leprosy, and varicella zoster virus. Cutaneous cryptococcal infection needs to be excluded in patients with AIDS as an MC-like eruption has been described in several such cases.<sup>33</sup>

### Treatment

Treatment of MC is not needed as spontaneous resolution is the norm in most cases. Patients need to be reassured that the lesions may take a few months to resolve and can be left to heal naturally.

Circumstances where treatment may have to be considered are mainly cosmetic in nature and are cases with underlying atopy.

The goal of treatment is the destruction of the lesion to prevent further transmission and auto inoculation.<sup>34</sup> Most of the available treatments employed traumatize the lesions and speed up the healing process. Antiviral and immune-modulating treatments have recently been added to these options.

Currently, there is no evidence to suggest a superiority of one treatment over another in MC. A recent Cochrane review of treatment interventions (495 patients) highlights that many of the current treatment modalities practiced, including physical destruction, have not been adequately evaluated. Several of the treatments reviewed are not routinely practiced. None of the treatment options had any serious adverse effects. The authors also acknowledge the limitations of the studies as being small numbers of patients, investigators not blinded, and patients not completing the study (were numerous in some studies) excluded in the total analysis.<sup>35</sup>

The choice of treatment is mainly dependent on physicians' experience, patient preference, and the availability of therapy. In view of lack of objective evidence, many of the treatments detailed below are not routinely used in the UK.

*Topical treatments* that have been shown to be effective are discussed below in no particular order of efficacy:

- (a) *Home-based topical treatments* that are currently available include
  - (i) *Podophyllotoxin cream (0.5%)*: Podofilox is an alternative to podophyllin and can be safely self-applied by the patient at home. The treatment consists of the application of 0.05 ml of 5% podofilox in lactate-buffered ethanol twice a day for 3 days.<sup>36</sup> It is important

to ensure that when prescribing for women, adequate contraception is recommended as the use of this agent is contraindicated in pregnancy. Occasionally some irritation may be noted.

(ii) *Imiquimod cream (5%)*: This immunomodulator cream acts by inducing high levels of IFN and cytokines locally and has recently been added as a topical home treatment option to treat MCV. It is self-applied to the affected area nightly for 4 weeks, and patients need to be informed that clearing can take up to 3 months. Though well-tolerated, application site irritation is a common side effect and, like podofilox, its use in pregnancy is not advocated.<sup>37</sup> No toxic effects have so far been reported following its use in children.

(b) *Podophyllin*: This is available as a 25% suspension in a tincture of benzoin or alcohol and contains mutagens such as quercetin and kaempferol. It is applied topically and used once weekly. Its use is advisable under medical supervision as some of the side effects include severe erosive damage in the adjacent normal skin causing scarring. Systemic effects such as peripheral neuropathy, renal damage, adynamic ileus, leukopenia, and thrombocytopenia have been reported with its use, especially on large mucosal surfaces.

(c) *Cantharidin*: This comprises a 0.9% solution of cantharidin and acetone. It is a blister-inducing agent that needs to be applied sparingly to the dome of the lesion with or without occlusion and left in place for at least 4 hours before being washed off. It should be applied only after a test dose on a few individual lesions before treating several lesions, especially those on the face, as treatment has been known to cause severe blistering. If tolerated, treatment is repeated every week or repeated once or twice every 3–4 weeks until the lesions clear. Usually one to three treatments are necessary.

(d) *Tretinoin cream*: Tretinoin 0.1% and 0.05% cream has been successfully used when applied daily or twice daily to the lesions. Erythema of previously treated lesions is a noted side effect though less irritation has been associated with the 0.05% cream.

## Evisceration Methods

An easy method to remove the lesions is eviscerating the core with an instrument such as a scalpel, sharp tooth pick, edge of a glass slide, or any other similar instrument capable of removing the umbilicated core.

- Expression of the pearly core, either manually or using forceps and piercing with an orange stick, with or without the application of tincture of iodine or phenol can also be considered.
- *Iodine solution*: The following technique has been recommended when an iodine solution and salicylic acid is available. 10% Iodine solution is placed on the molluscum papules and allowed to dry, and the site is covered with 50% salicylic

acid plaster. This process is repeated daily until the papules become erythematous, usually in 3–7 days. After this, only the iodine solution is applied. Resolution of lesions has been reported within a 26-day period.

- Similarly, aqueous potassium hydroxide 10% solution can be applied topically to a lesion. Resolution has been seen to occur within a month.
- Tape stripping has been successfully used in treatment and involves the use of an adhesive tape that is repeatedly applied to and removed from the lesion for 10–20 cycles. This removes the superficial epidermis from the lesion but can lead to secondary skin infection.

Because of the simplicity of the above-mentioned techniques, patients, parents, and caregivers may be taught these. These methods, though simple, may not be tolerated by children.

## Cryotherapy with Liquid Nitrogen

Cryotherapy can also be utilized and requires a halo of ice to surround the lesion for maximal effectiveness but can be painful. Repeat applications may be necessary and are carried on a weekly basis. It can be, however, safely used in pregnancy and may need local anesthesia.

## Curettage or Diathermy of the Lesions

Curettage, with and without light electrodesiccation, can be used to treat MC. This method is painful, requiring topical anesthetic cream prior to the procedure. In cases where the diagnosis is uncertain, this may be the preferred treatment method, having the advantage of providing a reliable tissue sample.

## Pulsed Dye Laser

The use of pulsed dye laser has demonstrated some excellent results with reports of 96–99% of lesions responding after just one treatment. It is well-tolerated with no adverse side effects including scarring noted. Majority of the lesions resolve within 2 weeks. However, its prohibitive expense makes it less cost-effective than other options.

## Systemic Drug Treatment

### Cimetidine

This oral histamine<sub>2</sub>-receptor antagonist acts by stimulating the delayed-type hypersensitivity. A single small uncontrolled study has shown resolution in nine out of 13 patients with cimetidine 40 mg/kg/day in two divided doses for 2 months. The use of systemic treatment in treating MC is currently not indicated as the efficacy of cimetidine is still to be determined.

In patients with HIV infection and MC, several studies have shown the introduction of HAART and the subsequent immune restoration leading to the resolution of MC lesions.<sup>38–40</sup>

## Prevention and Control Measures

Patients must be advised to avoid scratching and sharing of grooming implements and personal items. Measures to control the activity of infected cases are not required as the risk of transmission is very low. It may, however, be reasonable to advise/consider suspending an infected individual's sporting activities only in an outbreak situation.

# Hepatitis Viruses

Gary Brook • Yogesh Chawla

## Hepatitis B Virus

Hepatitis B infection is a global health problem with more than 350 million hepatitis B virus (HBV) carriers worldwide. It is a DNA virus that infects the liver causing hepatocellular necrosis and inflammation. HBV infection can either be acute or chronic, ranging in severity from being asymptomatic to symptomatic and completely resolving to severe, progressive, and even fatal illness.

### MOLECULAR BIOLOGY

HBV is the prototype of hepatotropic DNA viruses (hepadnaviruses). The replication strategy and life cycle of HBV has been studied in animal models, such as woodchuck, duck, and ground squirrel.

### Physical Characteristics

HBV is a hardy virus. Its infectivity persists for many years after plasma storage at  $-20^{\circ}\text{C}$ . It resists heating to  $60^{\circ}\text{C}$  for up to 4 hours, but if heated for 10 hours it would lead to inactivation of a small amount of HBV. Autoclaving and thorough cleansing of equipments, followed by submerging in hypochlorite or glutaraldehyde solution, are good and acceptable methods to inactivate the virus. Three types of viral particles are visualized in infectious sera under electron microscopy.

1. The infectious virion is a 42 nm spherical, double-shelled structure called the Dane particle. The outer shell is the HBsAg (surface antigen), which surrounds the inner core protein (HBcAg, core antigen) containing nucleocapsid.
2. Two other non-infectious particles, which outnumber the Dane particles, are seen as spherical structures of 20 nm diameter and filaments of variable length with a width of 20 nm. These filaments and spheres are composed of HBsAg and host-derived lipids only.

### Genomic Organization

The HBV genome is a partially double-stranded DNA with cohesive 5' ends that maintain a relaxed circular structure.

The viral genome (Fig. 32.1) has a compact organization of four overlapping open reading frames (ORFs) which function as follows:

1. Surface: encodes envelope surface proteins, HBsAg (S-ORF)
2. Core:
  - Precore—encodes HBeAg (C-ORF)
  - Core—encodes HBcAg
3. Polymerase: encodes HBV-DNA polymerase (P-ORF)
4. HBx: a transcriptional activator that probably takes part in oncogenesis (X-ORF).

After an exposure, the virus gains access to the liver *via* the blood. The virus attaches itself to the hepatocyte through

Fig. 32.1: HBV-genome.

the elements of pre-S1 and pre-S2 genes. Sialoglycoprotein receptors on the hepatocyte mediate the uptake of HBV possibly by endocytosis. On entering the hepatocyte, the nucleocapsid is delivered to the nucleus and the viral genome is repaired to form a covalently closed circular DNA (cccDNA). These are transcribed to pregenomic RNA and translated to HBc and *pol* proteins. Viral transcripts are translated in the cytoplasm and the core and polymerase proteins interact with the genomic RNA to form new capsids. Reverse transcription occurs and the mature virions are assembled in the endoplasmic reticulum, where they acquire the surface proteins and are released from the hepatocytes into the circulation by exocytosis.<sup>1</sup> During viral replication, some of the double-stranded HBV-DNA may become integrated into the host chromosomal DNA. This integrated HBV-DNA is possibly responsible for the development of hepatocellular carcinoma (HCC) many years later. The supercoiled cccDNA is not reduced by treatment with reverse transcriptase inhibitors, like lamivudine, which is active only in suppressing viral DNA synthesis and thus HBV replication, but not in eliminating the virion. Thus, these drugs may be suppressive rather than curative. However, cure can occur in patients with suppressed virus through immune clearance. HBV also replicates within the mononuclear cells of the bone marrow or blood, but liver is the primary site of HBV replication.<sup>2</sup>

### HBV Genotypes and HBsAg Subtypes

The genome of HBV is relatively stable. There are seven genotypes A to G based on an intergroup divergence of 8% or more in the complete nucleotide sequence. These genotypes have a geographic distribution as given below:

- A:** Northwest Europe, North America, Central Africa, India;
- B:** China, Japan, Indonesia;
- C:** China, Japan, Korea;
- D:** Mediterranean Basin, Middle East, India;
- E:** Africa;
- F:** American natives;
- G:** United States, France.

Response to antiviral treatment and pathogenesis may vary between different genotypes.

All HBsAg subtype determinants share one common antigenic determinant 'a'. In addition, two pairs of mutually exclusive subtypic determinants 'd' or 'y', and 'w' or 'r' also correspond to typical alleles within the S domain, but they do not clearly correlate with the genotypes. Thus, of the four possible major subtype combinations only three, *ayw*, *adw*, *adr*, have been found with any degree of frequency and these occur in distinct but possibly changing geographic and demographic distribution.

### EPIDEMIOLOGY

The carrier rate of the HBV ranges from 0.1% to 20% in different parts of the world. The HBsAg carrier rate has been found to

be between 1.1% and 12.2% in the general population of India. In high prevalence areas (>8%), i.e., Southeast Asia, South America, and sub-Saharan Africa, perinatal transmission is common, whereas in intermediate prevalence areas (2–7%), like the Mediterranean region, Japan and India, percutaneous and sexual modes of transmission are common. Low prevalence areas (<2%) include northern Europe, US, Canada, Australia, and New Zealand. The mode of transmission in these areas is by the parenteral or sexual route. Several epidemiological studies have reported a decline in the HBsAg carrier rate in western and northern Europe and the United States. This may be due to safer sexual practices, behavioral changes, safe needle practices, vaccination, blood screening refinements, and the use of virally inactivated components.<sup>3</sup> Universal vaccination in some countries has also significantly decreased the HBsAg carrier rate.<sup>4</sup>

### ROUTES OF TRANSMISSION

Transmission of HBV is largely through three routes: vertical (mother to child), sexual, and parenteral.<sup>5–9</sup> In a significant proportion of infected people, the exact route of acquisition is unknown. For transmission to occur, there must be a source, an effective mode of spread and a susceptible host.

### Parenteral Transmission

The source of HBV infection is mostly blood from chronic carriers of HBV. HBV is present in large amounts in the blood, and even a single and minute exposure can transmit the infection. Infectivity correlates with the Hepatitis B viral load in the blood. Patients with HBeAg in addition to HBsAg generally have a higher viral load ( $>2 \times 10^4$  IU/ml), which explains why transmission occurs even with a minor needle stick exposure from an HBeAg-positive individual. Patients who are anti-HBe positive usually have HBV in low titers and thus require a large amount of blood for transmission to occur, except for those with the precore/core-promoter mutant (see below) which can be highly infectious.

HBV has rarely been transmitted from HBsAg negative but anti-HBc positive blood, which represents low levels of infection, such that the virus is present but the HBsAg is in too small amounts to be detected by the routine ELISA kits. Transmission may also occur from HBsAg-negative blood transfusion if the source is in the "window period" of HBV infection.

HBsAg can occasionally be found in very low concentrations in the urine, breast milk, vaginal secretions, cerebrospinal fluid, sweat, tears, bile, and feces, however these secretions have not been proven to be infectious. Semen has been reported to transmit HBV infection (see below), but the amount of virus is 100–1000 folds less than in blood.

Parenteral transmission, thus, can occur after blood transfusions, exposure to untreated plasma products (e.g., factor VIII, factor IX concentrates, and cryoprecipitates), sharps, incidents such as needle-stick injury accidents and exposure to contaminated unsterilized instruments, such as those used in tattooing, acupuncture, ear piercing, or dentistry. Outbreaks of

HBV infection have been ascribed to gynecological surgery or dentistry, when the surgeon is HBsAg- and HBeAg-positive. Transmission has also been reported from HBeAg-negative but HBV-DNA-positive surgeons.<sup>8</sup> Men with hemophilia, who frequently require factor VIII concentrates, had a high incidence of HBV infection in the past before the introduction of treated products and factors created through recombinant technology. Injecting drug abuse is also a recognized source of HBV infection due to the sharing of drug paraphernalia.

## Sexual Transmission

Sexual activity is the most important mode of HBV transmission in areas of low to intermediate prevalence of infection. The manner by which HBV spreads by sexual activity is unclear. HBV is detectable in semen, but spread is higher if there is a break in the skin or mucous membrane of the susceptible host. Thus, the sexual activity most frequently incriminated in HBV transmission has been anal intercourse, especially for the receptive partners.

With heterosexual activity, the spread occurs when HBV in semen or vaginal secretions is probably associated with minute penile or vaginal lacerations. Factors associated with a high risk of viral acquisition in the homosexual population include multiple sexual partners, anal receptive intercourse, and the duration of sexual activity. In the last two decades, as a result of changes in the sexual behavior in response to the AIDS epidemic, viral transmission through this route has decreased considerably in many countries. Presently, heterosexual exposure accounts for the majority of sexually acquired cases in the developed nations. In heterosexuals, factors associated with an increased risk of HBV infection include the duration of sexual activity, the number of sexual partners, a history of other sexually transmitted diseases (STDs), and a positive serology for syphilis.

Sexual partners of injection drug users, commercial sex workers and their clients are particularly at a high risk for infection. Studies of household and sexual contacts of HBsAg carriers have shown that 0–3% of the spouses or sexual partners and 4–9% of the children are HBsAg-positive. More significant is the fact that there is a very high prevalence of markers of prior HBV infection (anti-HBc) in these two groups (30–60% in spouses or sexual contacts and 10–15% in children). These people who are unaware of their infection with HBV form an important source of HBV transmission worldwide. As with perinatal transmission, sexual transmission is also facilitated by active viral replication (high HBV-DNA/HBeAg positivity) in the infected individual.

The use of condoms appears to reduce the risk of sexual transmission. By cloning and sequencing the polymerase chain reaction (PCR)-amplified HBV-DNA, 100% sequence homology of HBV-DNA has been found in both HBV-infected index patients and their spouses. This provides direct evidence of sexual transmission of HBV. HBV appears to be more readily spread by sexual contact than does human immunodeficiency virus (HIV) or HCV as shown by the higher rates of antibodies to hepatitis B than against HIV or HCV among sexual contacts of men with hemophilia and drug addicts.

## Inapparent Transmission

Inapparent spread may occur in the family or in other settings although the route is unclear. This inapparent spread is more likely to occur in children. The role of bed bugs as a source of transmission cannot be dismissed in some countries, although is not proven. In less developed countries, poor hygiene, shared utensils, frequent skin diseases, shared razors, scarification by tribal and traditional healers, tattooing, and acupuncture may spread hepatitis B. The feces of chronic HBsAg carriers is not the source of infection. Infection also does not spread through casual contact, such as touching, hugging, kissing, sharing towels, or food.

## Perinatal (Vertical) Transmission

This is a very important mode of transmission, especially in areas where the HBV prevalence is high. Infection correlates with HBV viral load and is especially high if the plasma HBV-DNA is  $>2 \times 10^4$  IU/ml. The HBsAg positive mother is likely to transmit the infection to the neonate in 90% of cases, if she has a replicative HBV, as detected by HBeAg positivity or a high viral load. The transmission to the neonate is less likely if the mother is HBeAg-negative and has a low viral load. Infected babies are typically asymptomatic and have a 90% chance of developing chronic infection, in contrast to adults who have only 5–10% chance of developing chronicity. The infection is mostly acquired by the infant by inoculation of the infected maternal blood and liquor during passage through the vagina, rather than intrauterine transmission.

## DIAGNOSTIC SIGNIFICANCE OF HBV SEROLOGICAL MARKERS

### HBsAg

If HBsAg is positive for the first time, a second serum sample should be requested to exclude errors. This should be accompanied by IgM anti-HBc, which, if also positive, indicates acute viral hepatitis due to HBV (Fig. 32.2). HBsAg positivity without IgM anti-HBc indicates that the patient is an HBsAg carrier. With current diagnostic assay systems such as enzyme immunoassay (EIA), as little as 1 ng/ml of HBsAg can be detected.

### HBV-DNA

This is the most sensitive test for diagnosing HBV infection, which can be used to clarify issues if the antibody and antigen tests are not completely helpful. The presence of HBV-DNA indicates HBV infectivity. Current assays can detect HBV-DNA to a sensitivity of 50 copies/ml (10 IU/ml). PCR is of use in diagnosing HBV mutants and in determining response to antivirals. It is expensive, which limits its use only to the technologically more sophisticated laboratories.<sup>9</sup>

### HBeAg

HBeAg positivity also indicates infectivity. It is very rare for HBeAg to be positive in the absence of HBsAg (Figs. 32.2 and

32.3). Hence, it should be tested only in patients who are HBsAg positive. However, there are HBV mutations (precore or core-promoter mutants) where the patient can be HBeAg-negative but still infectious with high-titer HBV-DNA.

### Anti-HBe

Anti-HBe, in acute hepatitis, generally indicates resolution of the disease and a good prognosis. It may be positive in patients with the precore/core-promoter mutants and HBeAg-negative chronic hepatitis patients. Such patients usually have raised aminotransferases and raised HBV-DNA.

### IgG Anti-HBc

It is found in both active and resolved HBV infections. Testing for anti-HBc is indicated if the prevalence of HBV infection is to be assessed in a community and can also be used as the screening test when testing for HBV infection.

### IgM-Anti-HBc

It is found in acute viral hepatitis B (Fig. 32.2) and its presence is a prerequisite to its diagnosis. It may also be positive in relapsing chronic hepatitis B.

**Fig. 32.2:** Schematic presentation of typical serologic course of acute self-limiting viral hepatitis B.

**Fig. 32.3:** Schematic presentation of typical serologic course of chronic viral hepatitis B.

### Anti-HBs

This is recommended to monitor the success of the hepatitis B vaccination but is also found in people who have recovered from HBV infection.

### PATHOGENESIS

Immunological factors play an important role in causing liver disease due to HBV. Peak HBV replication occurs well before peak cellular injury in acute hepatitis, suggesting that the disease represents immune lysis of infected hepatocytes. The mildest form of liver disease is often seen with the highest concentrations of the virus in the liver and serum, where the liver biopsy may have minimal or even no evidence of cellular necrosis, which suggests that HBV is not a cytopathic virus. The appearance of antibodies to HBsAg, with the disappearance of markers of HBV replication, also demonstrates a role for immunological clearance. A decrease in serum C3 and C4 reflects the formation of antigen-antibody complexes which may be constituted of HBsAg or other antigens of the HBV. Moreover, a strong, multispecific HLA1 and HLA2 restricted T cell response to several viral proteins accounts for cellular injury and viral clearance in acute hepatitis B.

In chronic hepatitis, the HLA class 2 restricted response in peripheral blood is relatively weak and is insufficient to clear replicating virus. In neonates, the suppression of cell-mediated immune response may favor infection, because the exposure to HBeAg induces tolerance to epitopes that are usually the target of cytotoxic T cell response at a time when the immune response is immature.<sup>10</sup> There is also some evidence of a failure of interferon production, which allows the synthesis of viral protein to occur unhindered with a poor display of HLA on the hepatocytes. Chronic infection is more common in immunosuppressed patients, patients on hemodialysis, post-renal transplant recipients, patients with leprosy or leukemia, and those with HIV infection.

### CLINICAL MANIFESTATIONS

The clinical manifestations and outcome of HBV infection depend on the age at infection, the immune status of the host, and the level of HBV replication. The spectrum of HBV infection during the acute phase varies from subclinical hepatitis, anicteric hepatitis, and icteric hepatitis to fulminant hepatic failure. During the chronic phase, it ranges from an asymptomatic carrier state to chronic hepatitis, cirrhosis, and ultimately HCC. The chances of developing chronicity decrease as the age at which HBV infection is acquired increases.

### COMPLICATED CLINICAL COURSE

- **Fulminant hepatitis:** It occurs in <1% and is associated with a high mortality.
- **Post-hepatitis syndrome:** Patients continue to have fatigue, anorexia, but their Liver Function Tests (LFTs) are normal.
- **Relapses:** They can occur in 1–3% of patients who return to full activity rather early or consume alcohol.
- **Chronic hepatitis:** Persistent detection of HBsAg for more than 6 months

## EXTRAHEPATIC MANIFESTATIONS OF HBV INFECTION

Ten to 20% of patients with HBV infection develop extrahepatic manifestations that are believed to be mediated by the immune complexes in circulation.

### Serum Sickness

It is seen in acute hepatitis B as fever, skin rash, arthralgia, and arthritis. This occurs in 5–15% of patients. The rash is urticarial, and arthralgias typically affect the wrist, elbows, knees, and ankles. Morning stiffness is common. Muscle pains and myositis may occur. The arthritis of acute hepatitis begins to improve with the onset of jaundice and resolves completely with no permanent deformity.

### Polyarteritis Nodosa (PAN)

It is rarely a complication of acute HBV infection. Vasculitis affects large- to medium-sized vessels of the cardiovascular system, kidney, gastrointestinal tract, central nervous system (CNS), and skin. Patients present with fever, polyarthralgia, rash, peripheral neuropathy, hypertension, and azotemia. HBsAg can be demonstrated in the vessels.

### Membranous Glomerulonephritis (MGN)

It is found especially in children. Approximately 30% of these children progress to renal failure, whereas 30–60% of children achieve spontaneous remission.

### Papular Acrodermatitis (Gianotti-Crosti Disease)

It usually occurs in young children below 4 years of age. It manifests as a symmetrical, erythematous, maculopapular, non-itchy eruption on the face, limbs, and occasionally the trunk. It lasts for 15–20 days along with axillary and inguinal lymphadenopathy.<sup>13</sup>

### Aplastic Anemia, Red Cell Aplasia, Thrombocytopenia and Agranulocytosis

They have been reported in patients affected with acute viral hepatitis. Pancytopenia usually occurs 2–12 weeks after the onset of jaundice.

### Neuromuscular Complications

They manifest as apathy, irritability, photophobia, and neck rigidity in acute hepatitis. Peripheral neuropathy, cranial nerve involvement, and Guillain-Barré syndrome have also been observed.

### Myocarditis and Pericarditis

Rarely, these have been described as also arrhythmias like atrial fibrillation and ventricular ectopics.

## Pleural Effusion

It can occur rarely that disappears after acute hepatitis has resolved. Acute pancreatitis may occur as a complication of fulminant hepatitis and HBsAg has been detected in the pancreatobiliary secretions.

## ACUTE HEPATITIS B

Only 30–50% of patients have icteric hepatitis, while 50–70% have anicteric or subclinical hepatitis. The course is divided into four phases.

1. **Incubation period:** It ranges from 40 to 140 days, but may be shortened by a large inoculum or prolonged with low-dose percutaneous exposure.
2. **Preicteric/prodromal phase:** This consists of constitutional symptoms, such as malaise, anorexia, nausea, vomiting, low-grade fever, myalgias, fatigue, and altered taste sensations. Some patients have a serum sickness like syndrome with fever, arthralgias (or frank arthritis), and a generalized erythematous maculopapular rash or urticaria. This prodromal period lasts for 3–7 days and is followed by the icteric phase.
3. **Icteric phase:** The constitutional symptoms start decreasing with the onset of jaundice. This period usually lasts for 2–3 weeks, but can be as long as 12 weeks, including a period of itching and clay colored stools.
4. **Convalescent phase:** This begins with the resolution of jaundice. The appetite increases and other symptoms disappear. Fatigue is the last symptom to disappear.

Physical examination in acute viral hepatitis reveals low-grade fever, icterus, and soft tender hepatomegaly. Sometimes, there may be mild lymph node enlargement. Patients with fulminant hepatitis may have features of hepatic encephalopathy and a decreased liver span. In patients with acute viral hepatitis, there is a 10–50-fold elevation in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) (ALT > AST). The prothrombin time is a good marker of prognosis. Serum bilirubin level rises to a peak and is also related to prognosis. Rarely, mild leukopenia with relative lymphocytopenia may occur and very rarely findings suggestive of hemolytic anemia may be present. The persistent elevation of ALT for more than 6 months suggests chronic liver injury.

Liver histology reveals lobular disarray, acidophilic degeneration of hepatocytes, focal lobular necrosis, portal and parenchymal infiltration by inflammatory cells (predominantly lymphocytes and macrophages), hypertrophy and hyperplasia of Kupffer cells, disruption of bile ductules, and cholestasis.

## Serological Diagnosis (Table 32.1, Fig. 32.2)

The first serological markers to be detectable in the serum is HBsAg, which appears during the incubation period,<sup>11</sup> HBsAg may last up to 5 months or even longer (Fig. 32.2). Concurrent

**Table 32.1:** Meaning of Serological Marker Results

Stage of infection	Surface antigen (HBsAg)	'e' antigen (HBeAg)	IgM anti-core antibody	Total anti-core antibody	Hepatitis B virus DNA	Anti-HBe	Anti-HBs	ALT
Acute (early)	+	+	+	+	+/++	–	–	
Acute (resolving)	+	–	+	+	+/-	+/-	–	
Chronic (immune tolerant)	+	+	–	+	++	–	–	N**
Chronic (immune active)	+	+	–	+	+	–	–	
Chronic (eAg negative)	+	–	–	+	+	+/-	–	
Chronic (inactive carrier)	+	–	–	+	-/+	+	–	N
Resolved	–	–	–	+	–	+/-	+/-	N
Successful vaccination	–	–	–	–	–	–	+	N

\*In very early infection the IgM anti-core can be negative.

\*\* N=normal.

with, or shortly after the appearance of HBsAg in serum, HBeAg and HBV-DNA become detectable. HBeAg is not found in the serum but is detectable in the liver in some patients with acute hepatitis B. The first antibody to appear during acute HBV infection is IgM anti-HBc that develops shortly after the appearance of HBsAg and persists for 6–12 months. IgG anti-core antibody (IgG anti-HBc) also appears early and often persists for life. Antibody to HBsAg (anti-HBs), which is protective against future infection, usually appears during convalescence after the clearance of HBsAg. The antibody to HBeAg commonly appears with the clearance of HBeAg and HBV-DNA from the serum.<sup>12</sup>

## CHRONIC HEPATITIS B

Five to 10% of adults exposed to HBV and 90% of neonates infected perinatally develop chronic infection. It is more common in men. Only a small percentage of patients with chronic hepatitis give a history of jaundice in the past, because in the majority the onset of infection is asymptomatic or mild. Patients with chronic hepatitis are asymptomatic or may have non-specific symptoms like fatigue that is intermittent, worsens with exertion, but is rarely disabling. They may have other symptoms such as nausea, anorexia, weight loss, jaundice, and low-grade fever. Many patients may be picked up after an executive health check up. With the development of cirrhosis,<sup>14</sup> there is weight loss, weakness, wasting, abdominal swelling, edema, jaundice, encephalopathy, and variceal bleeding. Occasionally, patients may present with HCC. Some patients may present with extrahepatic manifestations of hepatitis B.

There may be no physical signs but hepatosplenomegaly may eventually ensue. With more severe disease/cirrhosis, there may be spider angiomas, edema, abdominal swelling, and signs of portal hypertension, namely splenomegaly, distended veins over the abdomen, and ascites. Endoscopy may show esophageal varices.

Laboratory investigations reveal raised aminotransferases, which may be 5–8 times above the normal, with the alanine

aminotransferase higher than AST and an AST:ALT ratio of <1. Serum bilirubin and albumin are normal, but with increasing severity of liver disease both may become abnormal. With mild disease, the prothrombin time is usually normal, but would become abnormal as the liver disease worsens. If cirrhosis develops, the laboratory results become increasingly abnormal. The AST:ALT ratio becomes >1. Prothrombin time increases and serum albumin decreases with increasing liver dysfunction indicating a poor prognosis. Serological markers in chronic hepatitis B are helpful in defining the stage of infection and predicting the outcome.

Chronic hepatitis B is divided into four types<sup>15–17</sup> (Table 32.2 and Fig. 32.3), namely Type 1 (HBeAg-positive replicative/immune tolerant), Type 2 (HBeAg-positive immune active), Type 3 (low-replicative/inactive), and Type 4 (HBeAg-negative chronic active).

- **Type 1 (immune tolerant):** This phase is characterized by high levels of HBV replication but little or no evidence of active liver disease.

**Table 32.2:** Classification of Chronic Hepatitis B

Patient populations in chronic hepatitis B				
Marker	Immune tolerant (type 1)	Immune active (type 2)	Inactive HBsAg carrier (type 3)	HBeAg-negative CHB (precore/core-promoter mutant) (type 4)
HBsAg	+	+	+	+
HBeAg	+	+	–	–
Anti-HBe	–	–	+	+
ALT	Normal		Normal	
HBV DNA (IU/mL)	$>2 \times 10^4$	$>2 \times 10^4$	$<2 \times 10^2$	$>2 \times 10^3$
Inflammation on histology	Normal/Mild	Active	Normal	Active

- **Type 2 (immune active):** The ALT is high and liver biopsy shows evidence of inflammation and fibrosis. During this phase, spontaneous HBeAg clearance may occur accompanied by biochemical exacerbation (increase in ALT levels).
- **Type 3 (low replicating/inactive):** The virus replication greatly reduces in this phase. HBsAg remains positive. The ALT levels are normal, HBV-DNA levels are low, and the resolution of necroinflammation, as seen on liver biopsy, occurs. The annual rate of clearance of HBsAg is between 0.5% and 2% per year.<sup>16</sup>
- **Type 4 (HBeAg-negative chronic active):** Some patients may lose HBeAg and still have raised aminotransferases and HBV-DNA. These patients have precore/core-promoter mutant HBV and is common in Italy and Greece, but rare in the US and UK.<sup>17</sup> This is not as benign as was previously thought and 15–20% of patients ultimately develop cirrhosis in 5–20 years.

## Development of Hepatocellular Carcinoma

HCC is common in countries where chronic HBV infection is common. It occurs decades after the development of chronic hepatitis B. It is more common in men and in patients who acquire HBV infection in childhood. These patients present with a mass in the abdomen, decompensated liver disease, bleeding, or constitutional symptoms characteristically seen with any malignancy. About 80% have pre-existing cirrhosis but in 20% HCC arises in non-cirrhotic liver due to direct carcinogenic effects of HBV.

Abdominal imaging, such as ultrasound, is the most sensitive screening test. HCC can also be diagnosed by serum alpha-fetoprotein (AFP) although it is less sensitive than liver imaging. A progressive increase in AFP should raise suspicion of HCC in a chronic hepatitis B positive patient.

## TREATMENT

### Acute Hepatitis B

Patients with acute viral hepatitis are managed with supportive treatment. Most cases of acute viral hepatitis eventually resolve with the clearance of the virus and complete healing of the hepatic injury. However, in very severe cases with impending acute liver failure (ALF) antivirals, such as telbivudine, lamivudine, or entecavir, are indicated.

### Chronic Hepatitis B

The aim of treatment is to achieve sustained suppression of HBV replication and remission of liver disease. There are seven therapeutic agents approved for treatment of chronic hepatitis B with more under trial.<sup>18–23</sup>

#### Pegylated Interferon Alpha

The interferons have antiviral, antiproliferative, and immunomodulatory effects. Therapy with pegylated interferon

is indicated in patients who are (i) HBeAg positive with raised enzymes and (ii) HBeAg negative, HBV-DNA positive with raised enzymes (HBV precore/core-promoter mutants).

A response (virological) is achieved in 33–37% of patients, after pegylated interferon alpha therapy weekly for 48 weeks. HBsAg loss in these responders occurs in 7.8% of cases.<sup>18,19</sup> Nevertheless, a sustained response as demonstrated by normalization of transaminases and HBV-DNA clearance can be achieved in 15–25% of patients with mutant HBV (HBeAg-negative chronic hepatitis B), but long-term follow-up has shown a clearance of HBsAg in 15–30% of these sustained responders.<sup>20</sup> Interferons are expensive, which limits their use in resource poor areas. The response to interferon is likely to be poor in HBeAg-positive patients with normal enzymes and immunosuppressed individuals.

Interferons have complications like reversible bone marrow suppression. Flu-like symptoms are common, appear 4–6 hours after injection and diminish or disappear over 2–3 weeks of therapy, are dose dependent, and can be easily controlled with paracetamol. Psychiatric symptoms, such as irritability, anxiety, depression, psychosis, and suicidal attempts, that may be potentially dangerous, occur in 3–5% of patients. Rarely, acute renal failure, acute myocarditis, and bacterial infection may occur. Interferons are contraindicated in patients with concomitant severe extrahepatic illness, myelosuppression, thyroid dysfunction, psychiatric disorders, and autoimmune diseases.

HIV co-infection with HBV worsens the prognosis of liver disease and reduces the response rate to interferons.

#### Nucleoside Analogues

These drugs interfere with HBV replication by inhibiting the reverse transcriptase.

**Lamivudine (3TC)** It is effective although when used as monotherapy, resistance occurs at a high rate. It incorporates active triphosphate into the growing DNA chains, resulting in premature chain termination, thereby inhibiting HBV-DNA synthesis. It is of use in patients who are (i) HBeAg positive with raised aminotransferases, (ii) HBeAg negative, HBV-DNA positive with raised transaminases (mutant HBV), (iii) non-responders to interferon treatment, and with (iv) HBeAg-positive cirrhosis.

HBeAg to anti-HBe seroconversion and a marked reduction in HBV-DNA occurs in 17–32% of patients with an HBsAg loss of <1%, ALT normalization is seen in 41–72% of patients and histological improvement in 49–56% of patients. It is given in a dose of 100 mg orally, daily and should be administered for at least 1 year as a shorter duration of therapy is associated with lower rates of HBeAg seroconversion. A problem with lamivudine is the development of resistance that occurs in 14–32% of patients and manifests as a breakthrough infection defined as the reappearance of HBV-DNA in serum after its initial disappearance. It has a limited role in treating HBV infection due to its resistance profile.

**Adefovir** Given at a dose of 10 mg daily leads to HBeAg seroconversion to anti-HBe in about 15% after 48 weeks but will suppress HBV-DNA in 25–50% with 50% histological improvement and ALT normalization on long-term treatment. Resistance is much less common than with lamivudine, making it suitable for long-term suppressive treatment.

**Entecavir** It is very effective at a dose of 0.5 mg daily for treatment naïve patients and 1.0 mg daily for those with lamivudine-resistant HBV. 60–90% will show HBV-DNA suppression, 21% HBeAg to anti-HBe seroconversion, and 70% shows daily histological and ALT improvement after 48 weeks therapy. Acquired resistance is uncommon making this drug suitable for long-term suppressive therapy.

**Telbivudine** Although this drug, given at a dose of 600 mg daily, is very effective in the short-term, with a therapeutic response of about 70%, it is more prone to inducing resistant mutations than most of the other drugs and at a rate (28% at 2 years) which is only modestly less than lamivudine. It is therefore not suitable as long-term suppressive mono therapy.

**Tenofovir** This agent is more widely known and used for the treatment of HIV. At a dose of 300 mg daily it has an efficacy and barrier to resistance profile similar to entecavir. It is especially suitable, when given as part of triple anti-retroviral therapy, for the treatment of HIV/HBV co-infection.

**Emtricitabine (FTC)** Like tenofovir, this is an anti-HIV drug which is effective against HBV and is widely used in combination with tenofovir for the treatment of HIV/HBV co-infection as part of triple anti-HIV therapy. Its efficacy and resistance profile is similar to lamivudine. It is being considered as a treatment for HBV monotherapy.

**Combination Therapies** There is some evidence that combinations, such as adefovir plus lamivudine, may be more efficacious and lead to less resistance. However, the outcomes of clinical trials are awaited to clarify their status.

**HIV Co-infection** Most of these drugs have anti-HIV activity. Tenofovir, 3TC, FTC, and entecavir are all known to cause drug-resistant HIV if used as monotherapy. Telbivudine may also cause HIV treatment resistance although this is less clear. The only drugs that can be given alone in patients with HIV/HBV co-infection are adefovir and pegylated interferons. It is therefore crucial that all patients with HBV infection should receive an HIV test prior to starting therapy to prevent inadvertent induction of HIV drug resistance.

## PREVENTION

Hepatitis B vaccines are highly effective and provide protection against hepatitis B by stimulating the production of neutralizing antibodies against HBV.<sup>24</sup> Immunization reduces the incidence of hepatitis B by 90–95%.<sup>25</sup> Protection occurs with a rise in anti-HBs titers within weeks of the first 1–2 doses of vaccine. Protection titers for anti-HBs are >10 mIU/ml.<sup>26</sup> The vaccination can be

used for preventing perinatal transmission, where the vaccine should be administered within 12 hours of birth. In mothers who are HBeAg positive, hepatitis B immune globulin should also be given to the baby soon after birth.<sup>27</sup> The vaccine gives protection against HBV infection to an immunized individual for at least 5–10 years. Symptomatic hepatitis B is not observed in these immune individuals even if the anti-HBs levels fall to undetectable levels. This indicates that the vaccine establishes a good immunological memory and therefore some authorities suggest that the vaccine confers lifelong immunity after successful immunological response.

Subunit vaccines containing recombinant HBsAg produced in yeast have replaced the chemically inactivated HBsAg particle vaccines that were produced from chronic HBsAg carriers (plasma-derived vaccines). These recombinant vaccines are comparable in terms of safety and efficacy and adverse effects are fewer. Anaphylaxis is a rare complication. An immunization course includes three doses of the vaccine given at 0, 1, and 6 months or 0, 1, 2, and 12 months. Immune response may be reduced in persons over 40 years of age or those who are otherwise immunocompromised. These patients may benefit from a second course of vaccine or double doses of vaccine. Anti-HBs titer estimation is not routinely recommended following immunization except in high-risk individuals. The most effective strategy for controlling HBV infection is universal vaccination. In Taiwan, after universal vaccination, there has been an 80% fall in chronic HBV carriage in children, with similar decrease in childhood liver cancer.

## Hepatitis C Virus

Hepatitis C virus (HCV) was identified and characterized in 1989 by molecular techniques from chimpanzees infected with sera from humans with chronic non-A, non-B hepatitis. The virus is notorious for causing persistent infection in almost 85% of the patients leading to chronic hepatitis. These patients are likely to develop cirrhosis and HCC.<sup>28,29</sup> It is an enveloped virus belonging to the Flaviviridae family with a single-stranded RNA genome.

## GENOMIC ORGANIZATION

The HCV genome is a positive sense, single-stranded RNA of approximately 9.4 kb in length, with a single large ORF and highly conserved untranslated regions (UTRs) at the 5' and 3' ends (Fig. 32.4). There is little available detail on the replication cycle of HCV, as the virus undergoes a low-level replication in any cell culture system studied. B and T cell-derived lymphoid cell lines may permit HCV replication to a limited extent.<sup>30</sup> Significant heterogeneity has been observed among different HCV isolates leading to at least 6 genotypes identified as HCV 1 to HCV 6 and subtypes identified by lower case letters a, b, etc., based on the extent of nucleotide sequence divergence.<sup>31</sup> The genetic heterogeneity of HCV occurs because the HCV replication *via* the viral RNA polymerase is error prone, as the replicase lacks a proof reading exonuclease.

### EPIDEMIOLOGY<sup>31–35</sup>

The worldwide prevalence of chronic hepatitis C is 0.5–2.0% accounting for 150 million carriers in the world. All the genotypes are distributed in different geographic areas throughout the world. HCV 1 and HCV 2 are common in West Africa, Western Europe, North America, Australia, and Japan, HCV 3 in India, HCV 4 in Central Africa and Egypt, HCV 5 in South Africa, and HCV 6 in South East Asia. The infection is more prevalent in men, and there is evidence of age-related distribution of infection with minimal prevalence in childhood and progressively rising figures with increasing age.

The prevalence of anti-HCV is higher in high-risk groups (transfusion dependent) such as thalassemics (42–83%), men with hemophilia (50–95%), hemodialysis recipients (10–45%), injecting drug users (48–90%), tattooed persons (11%), prisoners (15–46%), and alcoholics (15–25%).<sup>32</sup> The prevalence of chronic HCV infection in patients with chronic hepatitis, cirrhosis, and HCC is very high in Europe and Japan (60–90%), intermediate in United States, Australia, and Africa (30–60%), and lower in China and other countries of the Far East (10–30%).

### ROUTES OF TRANSMISSION

HCV is efficiently transmitted by blood and blood products.

### Transfusion-Associated Transmission

In the past, HCV accounted for 85% of post-transfusion hepatitis, but this has now declined to 4%.<sup>36</sup> This is due to the exclusion of paid donors and the HCV screening of blood. It is still possible to miss some HCV-positive blood, if the donor is in the incubation period, for which screening with HCV-RNA would be needed. The risk is higher in transfusion-dependent hematologic disorders, such as thalassemia or hemophilia, but this has now been taken care of with the use of mandatory blood testing for HCV.

### Non-transfusion-Associated Percutaneous Transmission

#### Injecting Drug Use

Injecting drug use with the sharing of needles, syringes, and other paraphernalia is the most commonly identified risk factor

for HCV infection. Fifty to 80% of injecting drug users become anti-HCV positive within 12 months of initiating drug use and almost all are anti-HCV positive by 8 years.<sup>37</sup>

#### Healthcare Workers

Seroprevalence in healthcare workers ranges from 0.6% to 4.5% in some countries,<sup>38</sup> with dental surgeons having the greatest risk. Healthcare workers exposed to HCV positive blood after accidental needle sticks have an average seroconversion rate of 1.8% (range 0–6.6%).<sup>38,39</sup>

#### Hemodialysis

In the past, sharing of hemodialysis machines led to an increase in HCV infection among patients with renal failure. Nowadays, patients are routinely tested and if positive, for HCV, use machines designated for infected patient to prevent infection of those who are uninfected.<sup>40</sup>

#### Transplantation

Chronic HCV complicates hemodialysis patients at the time of renal transplantation.<sup>41</sup> The risk of acquiring new HCV has been reported to be up to 10% in the uninfected patients following transplantation, especially those receiving more than 5 units of blood or more than one kidney. About 50% of the organ recipients from donors positive for antibody to HCV develop hepatitis after transplantation, and therefore this is an exclusion criterion for donation.<sup>42</sup>

### Non-percutaneous Transmission

#### Sexual

The non-percutaneous modes of transmission include transmission between sexual partners and transmission from a mother to her offspring. The available evidence indicates that for HCV, as against HBV, transmission by non-percutaneous routes is inefficient and rare. This holds true for sexual transmission also.

Overall, the risk of HCV transmission with sexual activity is not clearly defined. Most sero-epidemiological studies have demonstrated anti-HCV in only a small number of sexual contacts of those who are HCV positive. In prospective studies of the sexual partners of HCV-positive people, the rate of transmission has been seen to be less than 1% per year, whereas HIV and HBV are transmitted much more readily. It is evident that sexual transmission is an important route of acquisition of HBV and HIV, but not of HCV.

Using PCR genomic amplification, the presence of HCV-RNA has been reported in saliva, vaginal secretions, and seminal fluid of infected subjects.<sup>43</sup> The results of these studies have been variable, because of the presence of possible inhibitors in the biological fluids, the levels of viremia and the number of HCV infected mononuclear cells in the studied samples. The risk of infection in the spouse of an HCV-infected person in a long-term monogamous relationship is about 4% (range, 0–27%).<sup>44</sup> Even in female sexual partners of men with hemophilia who

are infected with HCV, anti-HCV is detected in no more than 3–6%. In a Japanese study of spouses of 154 index patients with chronic hepatitis C, 27 (18%) were found to have HCV-RNA in the serum. Genotypic analysis was identical in 24 of the 27 pairs, suggesting transmission from the index patient to the partner. Another factor that has been found to determine the sexual transmission of hepatitis C is the pattern of sexual relationship. Sexual partners of index subjects without high-risk behavior (injection drug use or promiscuity) have anti-HCV prevalence ranging from 1 to 10%. In contrast, sexual partners of subjects with high-risk behavior have anti-HCV prevalence between 11 and 27%. Data also suggest that the sexual transmission of HCV, from male to female, may be more efficient than *vice versa*, which is similar to other blood borne viruses.<sup>45</sup>

Thomas et al.,<sup>46</sup> in a study of 309 non-injection drug using STD patients, found that 7% of the men and 4% of the women had anti-HCV. In logistic regression analyses, factors associated with anti-HCV positivity included age, greater numbers of lifetime sex partners, and HIV infection. Women, whose sex partners were anti-HCV positive, were 3.7 times more likely to have anti-HCV than those having anti-HCV negative partners. The proportion of RNA homology between anti-HCV positive females and their male partners was higher (94%) than among randomly selected patients (82%). The presence of genital ulcerations seems to increase the risk of sexual transmission of the HCV. Weinstock et al. have found that having sex with an injecting drug user having a history of gonorrhea and syphilis was associated with anti-HCV positivity on univariate analysis, but after controlling for confounding variables no such associations remained.<sup>47</sup>

Homosexual men have a higher rate of anti-HCV positivity as compared to monogamous heterosexual contacts. However, in this group, unidentified injecting drug use and multiple sexual exposures cannot be excluded. In a study of homosexual men, it was found that sexual risk factors for anti-HCV positivity included anal receptive intercourse, having an injecting drug using sexual partner, history of genital herpes, and HIV seropositivity. Sexual transmission of HCV in homosexual men is significantly increased as compared to the population controls, if the number of partners is more than 50. In the last decade, there has been a steady rise in many parts of the world of acute HCV infection in HIV-positive homosexual men and this is linked to traumatic anal sex, co-infection with ulcerative STDs [syphilis, herpes, lymphogranuloma venereum (LGV)], and recreational drug use.<sup>48,49</sup>

Sexual partners of injecting drug users (6%),<sup>50</sup> prostitutes and their clients (3.5–9% and 16%, respectively)<sup>51</sup> and heterosexuals with multiple sexual partners<sup>52</sup> have all been reported to be at an increased risk. The presence of HIV as co-infection enhances the sexual transmission of HCV.<sup>52,53</sup> The prevalence of anti-HCV and anti-HIV antibodies among female sexual partners of multi-transfused hemophiliac men was 2.6 and 12.8%, respectively. The risk of transmission of HCV was seen exclusively in those couples in whom the men were positive for both HCV and HIV antibodies. Thus, all women who were anti-HCV positive also had co-infection with HIV. The transmission of HIV alone was

not affected by the presence of co-infection with HCV in the male spouse. The authors concluded that the higher prevalence of HCV occurs in female sexual partners of men with hemophilia who have the co-infection of HCV with HIV.<sup>53</sup> The frequency of HCV transmission to sexual partners is 5 times higher when HIV is also transmitted, suggesting that HIV may be a cofactor for the sexual transmission of HCV. Sexual transmission of HCV in this setting is probably more effective because of enhanced viremia as a result of immunosuppression. In HIV positive individuals, the presence of injecting drug use further enhances the risk of acquisition of HCV infection. Overall, the data indicate that the sexual transmission of HCV does seem to occur, though rather inefficiently. The risk of acquiring HCV infection after a single sex act is negligible in most people although it can be high in HIV-positive homosexual men with high-risk sexual practices. Transmission of the HCV probably depends mainly on the viral load and that the level of viremia in most patients infected by HCV is probably insufficient for an effective sexual transmission.

### Perinatal Transmission of HCV<sup>54–57</sup>

In contrast to the high efficiency of perinatal transmission of hepatitis B from mother to infant, the rate of perinatal transmission of HCV infection is only 2–8%. High titers of circulating HCV in the mother may place the infant at a greater risk of acquiring HCV infection. A higher rate of perinatal transmission (36–44%) has been reported from mothers co-infected with HCV and HIV. Further studies are needed to delineate the time of infection (*in utero* or at the time of birth), the importance of breast feeding in neonatal transmission and the natural history of perinatally acquired HCV infection.

### Sporadic HCV Infection

One of the most vexing epidemiological questions is how HCV is acquired in approximately 40% of the patients, without identifiable risk factors.<sup>57</sup> Despite the screening of voluntary blood donors by questionnaires designed to exclude patients with risk factors for HCV infection, 0.5% are found to be anti-HCV positive. Sporadic HCV infection may result from a prevalent non-percutaneous or percutaneous route yet to be identified.

## NATURAL HISTORY OF HCV INFECTION<sup>58–63</sup>

This is largely based on previous studies of post-transfusion hepatitis, which reveals the silent nature of acute and chronic infections, precluding detection in the early stages of disease.

### Acute HCV Infection

It presents as asymptomatic transaminitis 2–26 weeks after exposure. The enzymes are elevated more than 15 times in 75% of patients. Less than 30% patients are symptomatic with constitutional symptoms such as anorexia, weight loss, abdominal pain, myalgia, and minimal jaundice. The symptoms are often indistinguishable from those due to hepatitis A or B. These symptoms usually resolve

over 1–3 months. Fulminant hepatic failure with HCV is extremely uncommon. HCV-RNA is the first to become detectable by PCR in acute hepatitis C infection, as early as 1 week after exposure. The antibody response to HCV is detected 4–8 weeks after exposure although it may be delayed for 3 or more months. Risk of chronicity has been estimated to be around 60–70%.

## Chronic HCV Infection

Only about one-third of patients have symptomatic liver disease, which is indistinguishable from other chronic liver diseases. Fatigue is the most common symptom followed by right-upper abdominal pain. Physical examination may reveal hepatomegaly in 30–70% of patients and splenomegaly in up to 15%. Jaundice is present in only 1% of cases. Patients in whom cirrhosis have developed may have a palpable liver, spleen, and stigmata of chronic liver disease. Serum ALT levels are normal in up to 30% of the patients, but there is a wide variability in enzyme elevation when patients are followed over time.

The histological features of chronic hepatitis C cover a spectrum of lesions ranging from non-specific and mild changes to chronic lobular, chronic persistent, and chronic active hepatitis with or without superimposed cirrhosis. Chronic hepatitis C usually displays less portal and periportal inflammatory activity and more lobular and degenerative changes. Macrovesicular steatosis, sinusoidal cell activation, eosinophilic granules, and bile duct lesions are the other lesions characteristically seen in patients with chronic hepatitis C.

Chronic hepatitis C exists in two different forms:

### 1. HCV carrier state with normal aminotransferases:

These patients are identified either during blood donation or at screening for HCV. Histologically, two-thirds of the patients show evidence of chronic hepatitis with one-third displaying normal to non-specific changes. These patients more commonly have genotype 2 or 3 and have a lower HCV-RNA load in the serum and liver and on follow-up may show an elevation of liver enzymes.

### 2. HCV carrier state with raised aminotransferases:

These patients have an unpredictable course. They may either have mild histological changes in the liver and are clinically asymptomatic, or may progress to severe liver disease that is symptomatic. The progression from acute hepatitis to cirrhosis or development of fibrosis may take 3 to 30 years. ALT values do not always predict the histological severity of the lesion. The outcome is more severe in patients infected via blood transfusion due to a larger virus inoculum and higher HCV replication as compared to those acquiring HCV through injecting drug use. Histology of the liver is the most adequate way to assess the stage and progress of chronic hepatitis, as most biochemical and virological parameters, like HCV genotypes, have uncertain prognostic values. More recently, transient hepatic elastography, an ultrasound-based technique to assess liver fibrosis, has been shown to correlate well with the results of liver biopsy.

Chronic hepatitis C is a slowly progressive disease with minimal clinical deterioration during the first 1–2 decades after infection.<sup>61</sup> However, survival in patients with decompensated cirrhosis is poor with only about 50% surviving for more than 5 years. HCC is a significant complication of HCV infection with the mean duration of HCV infection being 28–29 years and an annual risk of 1.4% in low-prevalence regions to 6.9% in high-prevalence areas, such as Europe and Italy.<sup>61,62</sup> The cofactors affecting the progression of HCV include alcohol intake that accelerates liver injury and probably also viral replication, male gender, age more than 45 years, ethnicity, host immune status, genotype 1b, and coexisting HIV infection.<sup>63–68</sup>

## EXTRAHEPATIC MANIFESTATIONS OF HCV

Chronic HCV has been associated with a number of extrahepatic disorders:

- **Autoantibodies:** Overall, 40–65% of patients with chronic hepatitis C are positive for antinuclear antibody, smooth muscle antibody, and anti-thyroid antibodies in low titers that represent an epiphenomena.<sup>69</sup>
- **Essential mixed cryoglobulinemia (EMC):** *Anti-HCV* is found in 42–54% and HCV-RNA in up to 84% of patients with essential mixed type II cryoglobulinemia. HCV-RNA has been demonstrated in the cryoglobulins of these patients. It is more frequent in patients with long-standing disease and suggests the chronic stimulation of B cells for the production of immune complexes. Clinically, EMC presents in 10–25% of patients as a triad of palpable purpura, arthralgias, and weakness with involvement of lungs and CNS. Interferon therapy results in decreased levels of cryoglobulins and an improvement in skin lesions.<sup>70</sup>
- **Cutaneous leukocytoclastic vasculitis (CLV):** It is probably the most common mixed cryoglobulinemia (MC)-related extrahepatic manifestation of chronic hepatitis C. It occurs in the presence of MC in 40–95% of such patients. The vasculitis appears as palpable purpura mostly on the lower extremities and can result in frank ulceration. It occurs as a result of the plugging of dermal capillaries with precipitated cryoglobulins.<sup>71</sup> HCV virus has been found in the IgG and IgM complexes and the severity of CLV correlates with the level of viraemia.<sup>72</sup> Such patients should be treated with interferon, which may eradicate the detectable virus.
- **Cryoglobulinemic renal disease:** Membranoproliferative glomerulonephritis has been reported in chronic HCV infection, both with and without MC, whereas MGN has been described only in patients without MC. Twenty percent of patients with chronic hepatitis C infection and MC have renal involvement, which is associated with a worse prognosis.<sup>73</sup> Interferon therapy is helpful.
- **Arthralgias:** Almost 50% of patients with chronic hepatitis C infection and mixed cryoglobulins complain of arthralgias, polymyositis, dermatomyositis, Behçet's syndrome, anti-phospholipid syndrome, and fibromyalgias. In a series from Israel, 31% of the 90 HCV patients had musculoskeletal symptoms.<sup>74</sup> Occasionally, patients with chronic hepatitis C and MC pres-

ent with arthralgias and high serum titers of rheumatoid factor and a mistaken diagnosis of rheumatoid arthritis is made. Joint involvement is usually non-migratory and symmetric. Ankles, wrists, elbows, hands, and toes are most commonly involved. These patients respond to antiviral therapy.

- **Neuropathies:** MC, in association with chronic hepatitis C infection, causes peripheral neuropathy in 10–20% of cases<sup>75</sup> manifesting as paraesthesias. The underlying vasculitis has been held responsible for cerebral infarction, stupor, mononeuritis multiplex, and cranial nerve palsies.
- **Pulmonary vasculitis:** These patients are extremely ill with multi-organ damage and develop respiratory failure that is progressive and refractory to treatment.
- **Sjögren syndrome:** Fourteen percent of patients with Sjögren syndrome have evidence of HCV infection.<sup>74</sup>
- **Porphyria cutanea tarda PCT:** This is the most common form of porphyria, which is characterized by the over production of porphyrins and their precursors. In France, Italy, and Spain, 70–90% of patients with PCT have been found to have chronic hepatitis C.<sup>69,76,77</sup> The prevalence is, however, less in Australia and New Zealand, where only 0–20% of patients with PCT have chronic hepatitis C infection. Possibly, HCV precipitates PCT by the production of antibodies against hepatic uro-D, an enzyme necessary in porphyrin metabolism. It is also due to virally induced oxidative stress and reduction in the redox potential of the hepatocytes.<sup>78,79</sup>
- **Lichen planus:** A 29% incidence of anti-HCV in patients with lichen planus was found from Italy compared to 3% in controls and 12% for hepatitis B.<sup>80</sup> Studies from UK have failed to reveal any association. The prevalence of HCV infection in patients with lichen planus thus varies from one geographic area to another.<sup>81</sup>
- **PAN:** It is rarely found in patients with chronic hepatitis C. In these patients anti-HCV positivity should be confirmed by HCV-RNA, because of likely false positivity for antibody testing. The prevalence of anti-HCV antibodies of 5–20% has been reported in patients with PAN.<sup>82</sup>
- **Prurigo:** This association has been known with chronic hepatitis C infection, as 11 out of 28 patients with prurigo (39%) had HCV infection as compared to only 5% of the controls.<sup>83</sup>
- **Other manifestations:** Urticaria, prurigo, erythema nodosum, and erythema multiforme have been occasionally reported in association with chronic hepatitis C.<sup>83</sup> An increased association of HCV and non-Hodgkins B cell lymphoma,<sup>79</sup> autoimmune thyroiditis,<sup>79</sup> lymphocytic sialadenitis with xerostomia,<sup>84</sup> and autoimmune thrombocytopenic purpura<sup>85</sup> have also been described.

## DIAGNOSIS<sup>85</sup>

HCV infection can be diagnosed by tests for antiviral antibodies (anti-HCV) and the direct detection of the virus genome in the serum, infected tissues and cells, and characterization of the genomic sequences of the virus to define the genotype and subtype.

- **Anti-HCV:** Serum antibodies are formed against a variety of non-structural and structural HCV antigens (Fig. 32.5). It is useful to diagnose past and present infection. Over the years, the sensitivity of ELISA kits to detect antibodies to HCV has improved. The third generation ELISA kits that incorporate antigens from NS3, NS4, and NS5 region have a very high sensitivity, except in patients who are in the early phase of infection before seroconversion or are immunocompromised. In these patients, serum HCV-RNA detection needs to be done for diagnosis. False-positive reactions are seen in patients with hypergammaglobulinemia, systemic lupus erythematosus, alcoholic liver disease, and metabolic disorders, as well as in pregnant women.
- **Serum HCV-RNA:** HCV-RNA is detected by PCR usually with primers derived from the more conserved 5' UTR of the viral genome.<sup>86</sup> HCV-RNA is helpful in diagnosing patients in the early phase of acute hepatitis C before seroconversion (Fig. 32.5), in immunosuppressed individuals, in patients with autoimmune disorders, those with hypergammaglobulinemia, and those on treatment with antivirals.
- **HCV genotyping:** This may help in prognosticating and planning the duration of antiviral therapy. HCV 1b genotype is more commonly seen in patients with severe liver disease including cirrhosis and HCC. These patients respond less well to therapy. Patients with the HCV 2 and 3 genotype are more frequently asymptomatic carriers with normal aminotransferases.

## TREATMENT

The aim of the therapy is to eradicate the HCV virus, thereby reducing liver injury, so that cirrhosis and HCC are delayed or prevented.

## Acute Hepatitis C Infection

More and more evidence is available that such patients should be treated with pegylated interferon alpha. One of the problems, while initiating treatment in acute hepatitis, is picking up such cases, as most of them are asymptomatic. A study, published by Jaeckel et al.<sup>87</sup> showed a 98% HCV-RNA clearance in 44 patients with acute hepatitis.

**Fig. 32.5:** Schematic presentation of typical serologic course of acute viral hepatitis C progressing to chronicity. HCV-RNA appears first in serum, followed by anti-HCV. ALT levels do not correlate with the activity and extent of liver damage.

## Chronic Hepatitis C Infection<sup>88–90</sup>

Treatment is with weekly pegylated interferon alpha plus daily ribavirin. Response rates of about 45% for genotypes 1/4 and 75–80% for genotypes 2/3 can be expected. Firstly, the decision has to be made about who to treat. For genotypes 2/3 all suitable patients should be offered treatment where available as the response rate is so high. Relative contraindications to therapy include psychiatric illness, continuing injecting drug use and severe illness including decompensated cirrhosis. For genotypes 1/4, given that the response rates are lower, therapy can be deferred if the liver disease is mild with little or no fibrosis on liver biopsy or hepatic elastography. Otherwise patients with liver fibrosis of grade 2 (Ishak score) or higher should be treated. The duration of therapy varies according to the viral genotype and virological response. The response is highest in patients with a rapid virological response (RVR) when the HCV-RNA is <50 copies/ml after 4 weeks therapy and with early virological response (EVR) when the HCV-RNA is <50 copies/ml or has fallen by  $>2 \times \log_{10}$  after 12 of weeks therapy. In genotypes 1/4 patients may be treated for 24 weeks if there is an RVR or 48 weeks if there is an EVR. If an EVR is not achieved, therapy can be stopped as it is unlikely to work. In genotypes 2/3, patients may be treated for 16–24 weeks if there is an RVR or 24 weeks if there is an EVR. If an EVR is not achieved, therapy can be also stopped as it is unlikely to work. In general, patients who are also HIV-positive have a lower response rate although this can be improved by ensuring that the CD4 count is as high as possible when treatment is started and by giving longer durations of treatment.

## Hepatitis A Virus

Hepatitis A virus (HAV) is a major public health problem throughout the world causing acute infection in millions of people every year. It is largely spread through the feco-oral route although it can be spread sexually in restricted circumstances. It is a small unenveloped RNA virus which is similar to the picornavirus family but is classified now in the hepatovirus genus.

## GENOMIC ORGANIZATION<sup>91</sup>

The HAV genome is about 7500 nucleotides long of positive sense RNA. It is polyadenylated at the 3' end and there is a VPg polypeptide at the 5' end. It comprises a single ORF which accounts for most of the genome and encodes for a single large polyprotein. This polyprotein is broken down to produce both structural and non-structural polypeptides. Replication takes place in the cytoplasm of the host hepatocyte. There is a single serotype but it can be divided into seven genotypes. However, there is a single dominant conserved epitope that stimulates neutralizing antibodies. HAV is resistant to environmental and acid degradation.

## EPIDEMIOLOGY<sup>92</sup>

HAV is endemic worldwide and the major route of transmission is feco-oral through food, water, and close personal contact.<sup>94–98</sup> Parenteral spread has been reported in injecting drug users, men with

hemophilia using contaminated factor VIII and other recipients of blood products.<sup>94–98</sup> These high-risk groups for parenteral exposure have in common a significant prevalence of chronic HBV and HCV infection. In patients with chronic hepatitis B or C or any other chronic liver disease, acute HAV infection can cause severe hepatitis leading to fulminant hepatic failure.

The disease severity and likelihood of symptoms is very much age-related.<sup>92</sup> For instance, only 5–20% of children under 5 years old will develop jaundice during acute infection and HAV-related mortality is rarely seen in this age group. In highly endemic countries, infection typically occurs at a young age and therefore is usually without symptoms. Conversely, adult-acquired infection is much more frequently associated with symptoms including jaundice (possibly 75–90% of cases), though mortality remains generally very low at around 0.3%. Thus, HAV infection is associated with significant morbidity and greater risk of mortality when it occurs in older patients and in those with underlying chronic liver disease.

The worldwide prevalence of hepatitis A can be divided into five groups (Table 32.3). The WHO also recognizes three levels of HAV prevalence.<sup>92</sup>

## High Endemicity<sup>93</sup>

Developing countries with poor sanitary/hygienic conditions—parts of Africa, Asia, and Central and South America. Infection is mostly in children and therefore usually mild or asymptomatic. Disease incidence may reach 150/100,000 population per year with approximately 1 million cases per year in these areas.

**Table 32.3:** Patterns of Hepatitis A Endemicity

HAV endemicity	Epidemiological patterns by region	Average age of patients (years)	Usual routes of transmission
Very high	Africa, parts of South America, the Middle East, and of south-east Asia	Under 5	1. Person to person 2. Contaminated food and water
High	Brazil's Amazon basin, China, and Latin America	5–14	Person to person Contaminated food and water Outbreaks
Intermediate	Southern and Eastern Europe, some regions of the Middle East	5–24	Person to person Contaminated food and water Outbreaks
Low	Australia, USA, and Western Europe	5–40	Common source outbreaks
Very low	Northern Europe and Japan	Over 20	Exposure during travel to high-endemicity areas, uncommon source

## Intermediate Endemicity

Countries where sanitary conditions are variable—South and East Europe, parts of the Middle East. Many children escape infection, therefore clinical disease incidence may be high as infection occurs more frequently in adults.

## Low Endemicity

Countries with good sanitary and hygienic conditions—Northern and Western Europe, Japan, Australia, New Zealand, USA, and Canada. Infection rates are low and disease tends to occur among specific risk groups. Disease incidence of 5–10/100,000/year.

Improving levels of sanitation in many countries in the last decade have led to a fall in childhood HAV infection with a concomitant rise in adults susceptible to symptomatic disease and outbreaks.

## ROUTES OF TRANSMISSION

Feco-oral (via food, water, close personal contact) is the major route of transmission.<sup>94–98</sup> Outbreaks have been reported in men who have sex with men, linked to oro-anal or digital-rectal contact, multiple sexual partners, anonymous partners, sex in public places and group sex.<sup>99–105</sup> However, several seroprevalence studies in the UK, Spain, USA, and Italy show a similar rate of hepatitis A (IgG) antibodies in homosexual and heterosexual men.<sup>103,106,107</sup> HIV-positive patients are not at increased risk but may be more infectious.<sup>108,109</sup> Outbreaks have also been reported among injecting drug users, in institutions for people with learning difficulties, and in contaminated batches of factor VIII.

Patients are infectious for approximately 2 weeks before and 1 week after the jaundice by the non-parenteral routes but virus can be found in the blood and stool until after the serum aminotransferase levels have peaked.<sup>23</sup> In HIV-positive patients, Hepatitis A (HAV) viremia may continue for over 90 days.<sup>18</sup>

## Sexual Transmission

Men who have sex with men (MSM) are the group for whom there is the best evidence of sexual transmission of HAV, with numerous outbreaks reported.<sup>9–15</sup> In MSM, risk factors for HAV infection include visits to saunas and darkrooms, sex with anonymous partners, group sex, oro-anal and digital-rectal intercourse, and number of partners. The actual mechanism of sexual transmission remains uncertain but is presumably feco-oral and related to oral, penile, or digital contamination during sex. Reported outbreaks have been mainly confined to large cities including Melbourne, New York, London, Amsterdam, and Tokyo. However, the majority of MSM do not acquire HAV infection this way and there are several studies showing a prevalence of HAV-IgG (an indicator of past infection with hepatitis A) that is no higher in MSM than in heterosexual men attending STI clinics. For these routes of transmission, condoms are unlikely to prevent infection. There

is no evidence for heterosexual spread of HAV. As HAV is largely a childhood infection in many countries, unsurprisingly there is also no evidence for sexual transmission as a significant route of infection in adults in resource-poor countries.

## NATURAL HISTORY OF HAV INFECTION<sup>110–113</sup>

The incubation period of HAV is 2–6 weeks. Symptoms of acute hepatitis start with a ‘flu-like prodromal illness’ (malaise, myalgia, fatigue), often with right-upper abdominal pain which can last for 3–10 days.<sup>114</sup> This is normally followed by icteric hepatitis (jaundice) for a few weeks which rarely lasts longer than 3 months. The jaundice is a mixed hepatic and cholestatic type and is associated with anorexia, nausea, and fatigue which usually last for 1–3 weeks. It can persist for 12 or more weeks in a minority of patients who have cholestatic symptoms of itching and deep jaundice.<sup>115</sup> Fever is not found in this phase.

Illness is very much age-related in HAV infection with only 5–20% of children under 5 years old showing symptoms. Adults are more likely to develop symptomatic hepatitis (75–90%) although the mortality is generally very low at around 0.3% of cases. HAV infection has a higher mortality when it occurs in patients over 40 years or those with chronic liver disease such as that due to hepatitis B, C, or alcohol. HIV does not influence the course of the illness.

Physical signs are non-specific in the prodromal phase with the patient showing evidence of fever and looking generally unwell. In the icteric phase, jaundice with pale stools and dark urine will be found. Liver enlargement/tenderness and signs of dehydration are also common. The fever will normally have resolved by the 3rd day of jaundice.

Complications of hepatitis A are relatively uncommon. ALF complicates approximately 0.4% of cases. Of those with acute icteric hepatitis, about 15% may require hospital care, of whom a quarter will have severe hepatitis (Prothrombin time [PT] > 3 seconds prolonged or bilirubin >170 mmol/L).<sup>116,117</sup> ALF due to hepatitis A is more common in patients already infected with chronic hepatitis B or C, although studies differ widely in measured rates.<sup>116,118</sup>

Chronic infection (>6 months) has only been reported in a tiny number of case reports.<sup>119</sup> The overall mortality is <0.1% although it rises to 40% on those with ALF unless they receive a liver transplant.<sup>116,117</sup> In pregnancy, the infection does not have any teratogenic effects but there is an increased rate of miscarriage and premature labor, proportional to the severity of the illness.<sup>120,121</sup> There have been case reports of possible vertical transmission.<sup>120,122,123</sup>

## EXTRAHEPATIC MANIFESTATIONS OF HAV

Extra-hepatic manifestations are very rare. There are reports of Henoch–Schönlein purpura and one case of cardiac failure attributed to hepatitis A.<sup>124,125</sup>

**Table 32.4:** Biochemical Features of Acute Viral Hepatitis

Test	Notes
Serum aminotransferases (ALT, AST)	Normally peak at 500–10,000 IU/L within the first 2 weeks. Takes up to 2–12 weeks to become normal
Serum bilirubin	Can be raised to >100 µmol/L. The bilirubin is both conjugated and unconjugated with bilirubinuria detectable. Prolonged jaundice may be seen in patients with the cholestatic variant of hepatitis. Jaundice may persist after aminotransferases settle
Serum alkaline phosphatase	Usually normal or only mildly raised (<300 IU/L) except in the uncommon cholestatic variant of acute viral hepatitis
Prothrombin time	May be slightly prolonged by 1–5 seconds. Prolongation >5 seconds (INR >1.5) reflects more severe liver damage and identifies patients who may be at risk for development of hepatic failure

## Diagnosis

Appropriate biochemical tests for suspected acute viral hepatitis are listed in Table 32.4. There are two serological tests for HAV: HAV-IgM and HAV total antibody.<sup>126–128</sup> (Table 32.5). In acute infection, the serum IgM anti-HAV antibody becomes positive during the prodromal illness and persists for up to 6 months.<sup>125–127</sup> Thus, positivity is indicative of recent infection. The total HAV antibody test becomes positive also within the prodromal illness but persists for many years and therefore a positive test does not distinguish between acute and past infection. Contacts of known cases (sexual, household, or other close contact) should also be tested. A positive total HAV antibody test signifies that the person is immune to hepatitis A.

### Screening of Asymptomatic People

At the STI clinic, the aim of screening is to identify those at risk by their sexual behavior in order that they may be offered vaccination if non-immune. Some clinics may choose to screen all MSM men. Others may choose to screen those MSM men

at highest risk, i.e., those living in areas where HAV in MSM is prevalent and also if they meet one or more of the following criteria: more than two partners within 3 months, anonymous partners, sex in public venues such as saunas or 'dark rooms', group sex, oro-anal, or digito-rectal sex.<sup>99–105</sup>

As injecting drug users are also at risk and may attend STI clinics as their only contact with health services, they also should be screened and vaccinated. The screening test for asymptomatic patients is serum total HAV antibodies and a positive result indicates natural immunity with no need for vaccination. If non-immune patients are vaccinated then there is no need for subsequent screening.<sup>126,128</sup> However, if vaccination is contraindicated or may not have worked (for instance in someone with HIV infection), then those with continuing risk should be asked to return for repeat tests should symptoms suggestive of acute hepatitis ensue in the future.

## TREATMENT

As most cases are mild or asymptomatic, treatment is normally based on rest and hydration. It is important to isolate patients as much as possible from people who are non-immune. There are no specific anti-viral treatments and so for severe cases, it is again a matter of supportive therapy. In the rare cases of ALF, supportive therapy should be offered in a specialized liver treatment unit with access to liver transplantation if available.

In pregnancy, women should be advised of the increased risk of miscarriage/premature labour and the need to seek medical advice if this happens.<sup>120,121</sup> Breast feeding can be continued and most children will have mild or asymptomatic infection.

## PREVENTION

Vaccination should be offered to all at risk.<sup>129–135</sup> If there is exposure to a known case of hepatitis A within the period 2 weeks before to 1 week after the onset of jaundice, post-exposure prophylaxis can be performed for at-risk household contacts or homosexual contacts (oro/anal, digital/rectal, and penetrative anal sex). The Hepatitis A vaccine schedule comprises doses at 0 and 6–12 months achieving 95% protection for at least 10 years (Table 32.6).<sup>129–135</sup> Current advice is to revaccinate after

**Table 32.5:** Confirmatory Serum Tests for Viral Hepatitis (Common Patterns)

Virus type	Acute infection	Chronic infection	Recovered/Immune
Hepatitis A	IgM anti-HAV +ve	Does not occur	IgG anti-HAV +ve. IgM anti-HAV –ve
Hepatitis B	IgM anti-HBc +ve, HBsAg +ve, HBeAg +ve, HBV-DNA +ve	IgM anti-HBc –ve (+ve low titer in flares) HBsAg +ve, HBeAg + or –ve, HBV-DNA+ or –ve	IgG anti-HBc +ve IgG anti-HBs +ve (may become negative) HBsAg –ve
Hepatitis C	IgG anti-HCV +ve by EIA (but may take up to 3 months or more). HCV-RNA +ve by PCR	As for acute infection	Antibody negative or IgG anti-HCV +ve by EIA. HCV-RNA –ve by PCR
Hepatitis D	IgG and IgM anti-HDV +ve HDAg +ve, HDV-RNA +ve With markers of acute/chronic hepatitis B infection	As for acute infection	Antibody, antigen, and RNA tests become negative within months of recovery

**Table 32.6:** Vaccine Schedules

Vaccine	Schedule	Advantages
Hepatitis A+ B	0, 1–6 months	90% or more response
	0, 1, 2, 12 months	May get a response within 3 months
	0, 1, 3 weeks, 12 months	May get a response within 1 month
Hepatitis A	0, 6 months	Fewer doses than the A+B vaccine

10 years<sup>128–135</sup> although there is increasing evidence that vaccine-induced immunity may be >20 years and possibly lifelong, so no further booster doses may be needed after the primary course in immunocompetent patients.<sup>129–135</sup>

The vaccine is formaldehyde-inactivated HAV grown in human diploid cells and is available as a single formulation or combined hepatitis A & B and hepatitis A & typhoid vaccines. All formulations seem to be equally efficacious.<sup>129–135</sup> They are given intramuscularly into the deltoid (not buttock) or subcutaneously if there is a bleeding disorder. In HIV-negative recipients, 95–100% will respond to a course of vaccine in terms of disease prevention. The commercially available test for serum total HAV antibodies is not sensitive enough to detect vaccine-induced immunity so vaccine response cannot be confirmed in clinical practice. Response rates to vaccination in HIV-positive people is reduced and this correlates with the CD4 count, with best response at CD4 counts >500 cells/mm<sup>3</sup>.<sup>136–138</sup> If patients with a low CD4 count (<300 cells/mm<sup>3</sup>) are vaccinated, they should be revaccinated if the CD4 count rises above 500/mm<sup>3</sup> as a result of highly active antiretroviral therapy or if the HAV IgG remains negative on retesting.<sup>136–138</sup> There is a low rate of mild injection-site reaction and rare transient systemic illness following vaccination and those with allergy to the vaccine or its components should not be vaccinated. There is also a combined A plus B vaccine which is given at 0, 1, and 6 months or 0, 1, 3 week and 12 months. Manufacturers recommend booster doses after 5 years although it is now widely held that in immune-competent patients boosters are not required (see above).

Given the unreliable attendance by many people using STI clinics it is best to give the first dose of vaccine at the initial clinic attendance to all those at risk of infection, especially if there is no history of prior vaccination or disease. The serum total HAV antibody test should be measured at the same time and the vaccination schedule can be continued or not, depending on whether this test subsequently shows the recipient to have been previously infected. Many patients at risk for HAV are also at risk for hepatitis B and so the combined A plus B vaccine would be an appropriate choice. However, if it is felt that the patient may not return for further doses then monodose HAV and monodose HBV vaccines should be administered as they contain more antigen and are therefore more likely to be effective after a single dose.

Human normal immunoglobulin (HNIG) 250–500 mg intramuscularly should also be considered for patients at higher risk of complications (concurrent chronic hepatitis B or C,

chronic liver disease or age >50 years), (Ib, A).<sup>129–131,133</sup> HNIG that is effective against HAV is in short supply and may only be available from public health authorities. HNIG works best if given in the first few days after first contact with an efficacy of 90% and is unlikely to give any protection more than two weeks after first exposure, but may reduce disease severity if given up to 28 days after exposure.<sup>129</sup> Patients are most infectious for two weeks before the jaundice (i.e., before the illness is recognized).

There is a combined Hepatitis A+B vaccine given on the same schedule as the hepatitis B vaccine and has similar efficacy to the individual vaccines although early immunity to hepatitis B may be impaired (IIa, B).<sup>139,140</sup> If an outbreak is suspected or if the index case is a food handler, notify the local public health department by telephone.

### Summary

The hepatitis viruses A, B and C are a major public health problem throughout the world causing acute and chronic infection in millions of people every year. All three infections can be spread sexually in specific circumstances. This chapter describes the three individual types of hepatitis in terms of their epidemiology, disease spectrum, and prevention.

Hepatitis A is caused by an RNA virus that is primarily transmitted by the feco-oral route but has also been shown to spread in sexual contact between men who have sex with men causing acute icteric hepatitis. Unlike hepatitis B and C, chronic infection is not a complication of this infection. Prevention is based on vaccination and hygiene.

Hepatitis B is caused by a DNA virus that is most commonly spread on a worldwide basis via the mother-to-child route although the sexual and parenteral routes are also important. It is equally infectious via unprotected penetrative vaginal and anal sex, mostly from chronic carriers. Approximately 5% of adults infected with hepatitis B will become chronic carriers although this rate is considerably higher in younger people and the immunocompromised. A significant minority also progress to liver cancer. This explains why there are approximately 350 million carriers worldwide, a million hepatitis B-related deaths each year and why liver cancer is one of the world's top 10 cancers. A further complication of hepatitis B is hepatitis D co-infection. This is often seen after parenteral transmission but sexually transmitted cases are being increasingly recognized. Hepatitis D leads to a more rapid progression toward cirrhosis and liver cancer. Both hepatitis B and D can be prevented by vaccination. Sexual transmission is additionally prevented through safer sex such as the uniform use of condoms.

Hepatitis C is caused by an RNA virus that is mostly spread via the parenteral route, especially in injecting drug users. Sexual transmission is largely confined to men who have sex with men and linked to frequent partner change, traumatic anal sex, and concurrent ulcerative STIs such as herpes, syphilis, and LGV. Acute infection is most often asymptomatic but about 80% of those infected become chronic carriers. With over 130 million carriers worldwide, this infection is also a leading cause of cirrhosis, liver cancer and death. There isn't an effective vaccine and so prevention is based on advice to those at risk- safer injecting practices for IDUs and safer sex for MSM.

## Introduction

Human cytomegaloviruses (HCMVs) are ubiquitous herpes viruses producing a variety of human infections in all age groups. The name of the virus is derived from its property of producing large intranuclear inclusions and smaller cytoplasmic inclusions, resulting in massive enlargement of the infected cells. It is a widespread opportunistic pathogen that causes no obvious clinical manifestation in healthy individuals. On the other hand, it poses an important public health problem because of the high frequency of congenital infections resulting in serious birth defects. Infections acquired after birth are generally mild and range from asymptomatic subclinical infection to a mononucleosis like syndrome in normal individuals but may be fatal in immunocompromised patients.

## History

Knowledge regarding this virus (Table 33.1) goes back to 1904 when big inclusion bearing cells were observed in the kidney, lung, and liver of infants who died of some disease, which was mistaken as congenital syphilis.

## Biology

### MORPHOLOGY

HCMV belongs to the family Herpesviridae, which are the largest DNA viruses grouped under  $\beta$  herpes viruses. It has the same

**Table 33.1:** History of Nomenclature of Cytomegalovirus

Year	Nomenclature
1904	<i>Entamoeba mortinatalium</i> (protozoa)
1921	Cytomegalia—large inclusion bearing cells in tissues
1926	Viral etiology—salivary gland virus
1956	Isolation of virus from human tissues
1960	Cytomegalovirus*

\*The term “cytomegalovirus” was proposed by Weller and colleagues to replace the term “salivary gland virus” which was misleading because the virus also involved other organs.

**Fig. 33.1:** Human CMV virion structure.

general structure as those of herpes viruses and demonstrates icosahedral symmetry. The size of the virus is 150–200 nm, significantly larger than that of herpes simplex virus (HSV). It has a 240 kb linear double stranded DNA genome, coding more than 70 viral proteins and has around 200 potential open reading frames.<sup>1,2</sup> The virion has a protein capsid, surrounded by a lipoprotein envelope containing a lipid bilayer and a number of virally encoded proteins (Fig. 33.1).<sup>3</sup> Between the capsid and the envelope is an amorphous layer referred to as the tegument. A cell surface glycoprotein, located within the tegument, acts as an Fc receptor that can nonspecifically bind to the Fc portion of immunoglobulins. This protein helps in immune evasion by the virus.<sup>4</sup> Antigenically related but genetically different strains of HCMV circulate in the human population. However, this may not have many clinical implications. HCMV can be distinguished from other herpes viruses by certain biologic properties such as host range and the type of cytopathology induced.

It has been demonstrated that HCMV contains not only DNA but also four species of mRNA, indicating that this virus is more complex than previously believed.<sup>5</sup> The virally encoded mRNAs are transcribed from one immediate early (IE) gene,

two early genes, and one late gene. Other herpes viruses may also contain similar types of mRNAs within their virions. However, classification of the herpes virus family will be affected by identification of viruses containing both DNA and RNA. It will be of great interest to virologists to discover the function that the virion mRNAs themselves or their protein products play in HCMV pathogenesis and may lead to new targets for treatment of herpes virus infections.<sup>6</sup>

## REPLICATION

HCMV replicates preferentially in human fibroblast cells *in vitro*. In laboratory cultures, it displays slow cellular replication, restricted cell tropism, limited cell to cell infection, and the presence of virulent virus within the cell. These *in vitro* properties of HCMV may reflect its limited pathogenicity in the normal human host. Cultures have to be incubated for a prolonged period, up to 50 days, as the cytopathic effects (CPEs) are slow in appearing. *In vivo*, the virus replicates in epithelial cells, especially in salivary glands, renal, and respiratory epithelium.<sup>7</sup> Replication is seen in the cell nucleus and it can cause either a lytic and productive or a latent infection. Large nuclear and smaller cytoplasmic inclusions are produced during replication.<sup>8</sup>

HCMV attaches to heparan sulfate receptors on the plasma membrane surface. As there are a variety of cell types susceptible to HCMV, it is possible that either there are a number of cellular receptors to which it can attach or they are distributed all over.<sup>9</sup> Penetration into the host cell involves fusion of plasma membrane and viral envelope. After penetration, the nucleocapsid is released into the host cell cytoplasm.<sup>9</sup> In the cytoplasm, the mRNAs are translated into proteins in the absence of gene products encoded by viral DNA. However, the function(s) of the mRNAs or their products is unknown. HCMV virions are then transported to the vicinity of the nucleus, where virus gene expression starts. Like other members of the herpes virus family, HCMV expresses three sets of genes,<sup>3</sup> i.e., immediate early (IE), early, and late genes. IE genes are first to be expressed. Their protein products have regulatory function in determining the expression of the next set of genes.

## Pathogenesis

The pathogenesis of HCMV infection is complex and starts with the penetration of the virus into the cell. Following infection, the virus resides in endothelial cells, macrophages or granulocyte stem cells.<sup>10</sup> Evading host immunity, it replicates to produce viral progeny. This is followed by spread of the virus to new cellular hosts within the body and to most of the organs.<sup>11</sup> Peripheral blood monocytes and circulating endothelial cells have been reported to be responsible for hematogenous spread.<sup>12</sup> Direct cell to cell contact has also been reported as mode of spread.

Like all herpes viruses, HCMV establishes a life long latent infection. Virus can be shed intermittently from the pharynx

and in the urine for months to years after primary infection. Latency is achieved after the acute phase of infection. Latent state in seropositive individuals is presumably maintained by the host immune response. Recently, bone marrow progenitor cells of the granulocyte/monocyte lineage have been shown to be the site of HCMV latency.<sup>13</sup> Besides this, HCMV has been shown to reside in vascular endothelial cells and bone marrow stromal cells.<sup>14</sup> Despite being thought to lie completely latent, the virus can be isolated from 61% of saliva samples,<sup>15</sup> 10% of uterine secretions, and 37% of urine samples<sup>15</sup> and is also found in blood, semen, vaginal secretions, milk, and stool.<sup>16–18</sup> This suggests that like HIV infection, the virus may occasionally cause a smoldering subclinical infection.<sup>19</sup>

The virus interacts with the host in the development of latency and further reactivation and replication. The latter occurs during favorable conditions and results in cellular damage.<sup>3</sup> This is caused either directly by viral lytic action or the host immune response. HCMV chorioretinitis in severely immunocompromised AIDS patients<sup>20</sup> is due to direct CPE of the virus. Immune mediated injury is the primary pathologic mechanism in HCMV pneumonitis.<sup>21</sup> Both direct and indirect mechanisms can combine to develop certain other manifestations.

Reactivation of HCMV is common and the virus is shed in various body secretions such as urine, saliva, semen, breast milk, and cervical fluid. The monocytes carrying HCMV in the latent state adhere to activated vascular endothelial cells. Next, they migrate into tissues where they differentiate into macrophages, thereby reactivating HCMV from the latent state and causing local CPE and intercellular transmission.

Reactivated infections are associated with disease more often in immunocompromised patients than in normal hosts. Depending upon the degree of immunosuppression, severity of reactivated infections varies from mild to severe. HCMV cooperates with other viruses by suppressing cell mediated immunity (CMI) and causing recurrences.<sup>22</sup>

HCMV infection in the fetus or in the newborn can be acquired from the mother with both primary and reactivated maternal infection. Maternal viremia may result in fetal infection in approximately one out of three cases of primary HCMV infection occurring during pregnancy. Although the most common cause of congenital infection is believed to be transmission of reactivated virus *in utero*, it seldom causes fetal damage. Generalized cytomegalic inclusion disease is the result of primary maternal infection. The greater severity of primary neonatal HCMV infection<sup>23</sup> might be explained by the facts that (i) latently-infected mothers give their children both virus and protective maternal IgG, (ii) viral titers are greater during primary infection so that infants receive more virions or perhaps, (iii) as in HIV infection, the virus evolves within the host because virions from primary infection are more virulent. The maternally derived immune response to HCMV determines both the frequency of transmission of the virus to the fetus (25–75%) and the virulence of ensuing infection. The finding that preconceptional serologic immunity can dramatically lower the rate of fetal infection but

not completely prevent intrauterine transmission, is unique to HCMV.<sup>24</sup>

## Host Immune Response

Immune response to HCMV infection is both humoral as well as cell-mediated and these along with natural killer (NK) cells play an important role in the immune control of HCMV disease.

### HUMORAL RESPONSE

Different types of antibodies to a variety of immunogenic HCMV proteins appear in human sera after infection. Most human sera have antibodies to envelope glycoproteins *gB* and *gH* and also to phosphoproteins.<sup>25,26</sup> Neutralizing antibody is mainly directed against the above glycoproteins and is associated with protection from infection and disease.<sup>27–29</sup> In organ transplant patients, HCMV infection is more frequent and severe when the donor is seropositive and recipient seronegative. Pretransplant immunization with live HCMV vaccine<sup>30</sup> and passive immunization with high-titer HCMV immunoglobulin<sup>31</sup> may prevent infection or reduce the severity of the disease in renal transplant patients. Maternal antibodies do not confer any protection against viral transmission as transplacental infection is probably carried by infected cells and is associated with high viremic load. However, development of serious disease can be prevented by maternal antibodies. Presence of antibodies in the breast milk does not prevent transmission to the neonate. Polyclonal activation of B cells by the virus contributes to the development of rheumatoid factors and other auto-antibodies during HCMV mononucleosis.<sup>8</sup>

### CMI

Both CD4+ and CD8+ T cell responses are found in seropositive patients. However, the CD8+ cytotoxic T lymphocyte (CTL) response is prominent and pivotal in the host defence against HCMV.<sup>32</sup> CD4+ T cells are necessary for the generation of this response.<sup>33</sup> Primary infection in late childhood or adulthood is often associated with a strong CTL response, resulting in the development of mononucleosis like syndrome. These CTL responses may contribute to immunopathology by reacting with the human leukocyte antigen molecules induced by HCMV. Progression of disease is associated with HCMV specific CTL responses.

There is some degree of immunosuppression associated with acute infection. During immunosuppression, the likelihood of reactivation from latency causing a variety of disease conditions is dependent on the viral load.<sup>34</sup> Antithymocyte globulin, a potent suppressor of CMI, may cause clinical HCMV syndromes.<sup>8</sup> Prevention of infection was achieved by successful transfer of CD8+ HCMV specific CTLs to immunocompromised bone marrow transplant recipients.<sup>35</sup> CTL immunotherapy has been found to decrease the viral DNA load in the organs and also

reduce the recurrence rate. However, complete DNA clearance could not be achieved.<sup>36</sup> HCMV may function as a cofactor to activate latent HIV infection.

### TARGET PROTEINS

Of all HCMV specific CTL responses, 70–90% recognizes the tegument protein pp65, which constitutes 95% of the tegument.<sup>37,38</sup> In addition, glycoprotein B (*gB*), the major envelope glycoprotein and pp150-tegument protein are also identified as targets.

### NK CELLS

The role of these cells in HCMV immunity was suggested by a case report of a NK cell deficient patient with severe HCMV and other herpes virus infections.<sup>39</sup>

### IMMUNE EVASION

HCMV may evade host's immune response resulting in the persistence of productive infection, viremia, and virus excretion for months or years.<sup>40</sup> This may be due to HCMV gene products that are responsible for this interference through several immunological mechanisms at different stages of the viral replication cycle.<sup>41,42</sup> Immune evasion strategies can be evasion of antigen presentation via interaction with cytokines or evasion of complement and humoral immunity.

## Epidemiology

The disease is endemic in all parts of the world, although it is never seen in epidemic form. Human beings are the only known host for HCMV. The prevalence of infection varies with socioeconomic status, living conditions, and hygienic practices. In developed countries, antibody prevalence varies from 40% to 80% in adults in high socioeconomic groups. In contrast, a prevalence rate of 90–100% in children and adults in developing nations and also in low socioeconomic groups in developed countries have been reported.<sup>3</sup> Overcrowding, poor personal hygiene, probable contact with infected urine and frequent breast feeding of infants may contribute to the high seroconversion rate.<sup>4</sup> In a major STD clinic in New Delhi, the prevalence of HCMV IgM antibodies in STD clinic attendees was found to be 17% in females and 8.5% in males.<sup>43</sup>

### MODE OF TRANSMISSION

The virus may be present in milk, saliva, feces, urine, and genital fluids. Asymptomatic viral carriage in semen and cervical secretions is common.<sup>8</sup> The common mode of transmission of the virus is either through sexual route by exchange of semen, vaginal fluid or saliva, or nonsexual routes like respiratory, through blood transfusion, sharing needles, organ transplantation, and perinatal. Transfusion of whole blood or certain blood products containing viable leukocytes may transmit HCMV with a

frequency of 0.14–10% per unit transfused.<sup>8</sup> The infection can spread through secretions containing free virions or cell associated virus.<sup>11</sup> Contact with infected maternal genital secretions during delivery and breastfeeding<sup>3,8</sup> are the two main routes of perinatal infection. Children in day care centers and at school often infect each other through saliva. Congenitally infected infants have viruria for up to 4–5 years. They are highly infectious in early infancy. In spite of prolonged contact, the virus does not spread readily among adults by ordinary nonsexual mode of transmission, as evidenced by failure of transmission to healthcare workers (HCWs) even by close contact with infected patients,<sup>3</sup> although variable reports exist. However, infected children can transmit infection to HCWs.<sup>44</sup> Risk of acquiring HCMV infection is more in immunosuppressed persons. A high percentage (90%) of kidney and bone marrow recipients develop infection probably due to reactivation of their own latent virus. Almost all AIDS patients are seropositive for HCMV.

### Sexual Transmission of HCMV

Sexual transmission occurs in heterosexuals, men who have sex with men (MSM), and women who have sex with women. MSMs have the highest infection rate. The risk of acquiring infection increases with the number of sexual partners. Although condoms, if used properly, help to prevent sexual transmission, the virus can be transmitted through kissing.<sup>45</sup> The following evidences have been cited<sup>3</sup> to prove that HCMV is an STI: (i) HCMV can be isolated from semen and there is increase in seroprevalence with commencement of sexual activity; (ii) nonsexual transmission of HCMV in adults is infrequent, e.g., absence of seroconversion in HCWs and military recruits in close contact with infected persons; (iii) isolation of HCMV from cervix of 13–23% of women attending clinic for suspected STIs and a higher rate (10–12% per year) of seroconversion among seronegative women with multiple partners attending an STI clinic versus 1–2% per year in the general population. The seroconversion was associated with acquisition of other sexually transmitted pathogens like *Chlamydia trachomatis*. Demonstration of transmission of HCMV infection to the female sex partners of a man with virus positive semen during the preceding 5 months and infection of a man after sexual contact with a woman whose cervix and urine were HCMV positive, strongly indicate sexual transmission. The development of HCMV proctitis in a woman who had vigorous receptive anal intercourse for 4 consecutive days and the isolation of different strains of HCMV from the same sexually active adult<sup>46</sup> suggest that reinfection may occur in heterosexuals. In addition, there is a higher rate of urinary excretion of HCMV and antibody prevalence in homosexual men (7.4% and 93.5%, respectively) than in heterosexual men (0% and 54.3%, respectively). A high attack rate of 71% during a 9-month follow-up of seronegative homosexual men and at the same time development of viruria in 32% of the seropositive group suggest increased transmission risks in homosexuals. The widespread occurrence of viruria and viremia (5 times more than urine) accounts for the extraordinary high attack rate of HCMV

infections among seronegative homosexual men. Estimated mean duration of semen positivity was 22 months against 9 months for urine. The exposure of the anorectal mucosa to HCMV infected semen constitutes the major route of acquisition of infection by homosexual men.<sup>47</sup>

### Congenital HCMV Infection

In a review of published studies,<sup>48</sup> the overall birth prevalence of congenital HCMV infection was 0.64% but it varied considerably among different study populations. About 11% of live-born infants with congenital HCMV infection were symptomatic. Non-white race, low socioeconomic status, premature birth, and neonatal intensive care unit admittance were risk factors for congenital HCMV infection. Birth prevalence increased with maternal HCMV seroprevalence. The rate of transmission to infants born to mothers who had a primary infection or a recurrent infection during pregnancy was 32% and 1.4%, respectively.

### REINFECTION

Several studies in homosexual men indicated that multiple strains of HCMV can be acquired as well as excreted by homosexual men with and without HIV infection.

### MOLECULAR TYPING

Infection and reinfection with multiple HCMV strains occur in immunocompromised individuals, STD clinic attendees, and children attending day care centers. HCMV clinical isolates were distributed into 30 different strains using PCR-restriction fragment length polymorphism (RFLP) analysis of multiple viral subgenomic regions. The number of isolates is not uniformly distributed among strains.<sup>49</sup> It is possible to determine the source of infection in the family by molecular epidemiology, i.e., by comparing DNA sequences of HCMV strains.<sup>50</sup> HCMV PCR-positive specimens from seropositive women were analyzed for glycoprotein gN and gB genotypes by cloning, followed by nucleotide sequencing of the plasmid DNA and/or RFLP. The results showed that most (93.7%) of the PCR-positive specimens contained multiple gN and/or gB genomic variants, suggesting that the majority of women were infected with more than one virus strain. The results also showed that the RFLP technique might not be sufficiently sensitive to detect all of the genomic variants present in a sample.<sup>51</sup>

### Clinical Features

Once HCMV enters a person's body, it remains life long. In most healthy adults, infection becomes latent, meaning that the virus remains in the body and there is potential for reactivation and recurrent illness in immunosuppressed patients such as in post-transplant cases or in HIV infected patients. The extent and severity of HCMV disease depends on the patient population.

## CONGENITAL INFECTION

HCMV is the most common microbial agent to cause congenital infection. Survey of congenitally infected neonates<sup>3</sup> has shown that only 10% have 'cytomegalic inclusion disease,' whereas the rest are without obvious symptoms at the time of birth. The chances of acquiring congenital infection and the extent of disease in the newborn depend on the immune status of the mother (Box 33.1). In the US, approximately 1% of all neonates excrete HCMV, of which 10% will be severely affected with a wide range of symptoms.<sup>53–55</sup> In UK, 400 HCMV affected neonates are born annually.

Infants with cytomegalic inclusion disease show signs of intrauterine growth retardation, hepatosplenomegaly, and thrombocytopenic purpura (60–80%) and may have jaundice, microcephaly, or chorioretinitis. They may develop severe hearing loss, mental retardation,<sup>54,55</sup> and ocular abnormalities. Prognosis among severely infected infants is grave and mortality rate may range from 20% to 30%. Premature infants may present with poor weight gain, respiratory distress, rash, fever, and hepatosplenomegaly, occasionally associated with *Chlamydia trachomatis*, *Pneumocystis jiroveci*, or *Ureaplasma urealyticum* infections.<sup>8</sup> HCMV excretion often persists for months or years.

## PERINATAL INFECTION

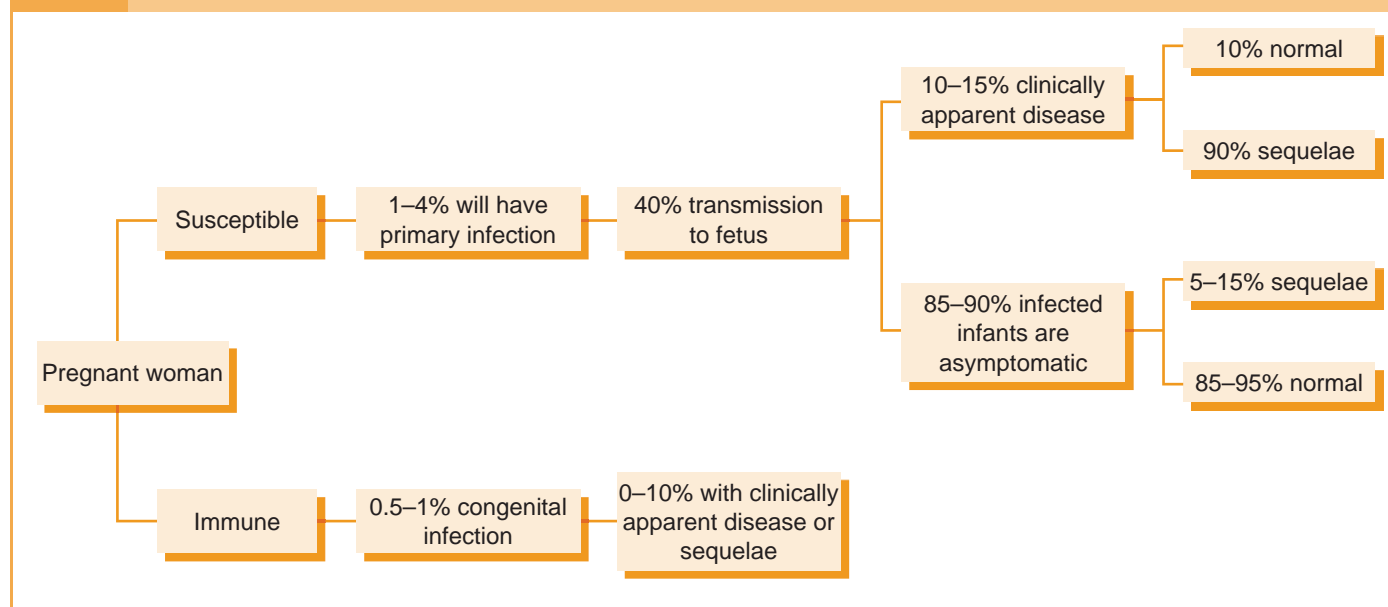

Full-term and otherwise healthy infants may acquire the infection during or shortly after birth by passage through infected birth canal or by postnatal contact with breast milk or other secretions, although they possess high titer of transplacentally acquired antibodies. Viral load in breast milk is an important factor for transmission of the virus.<sup>56</sup> These infants remain healthy but continue to shed the virus and sometimes develop learning

difficulties and deafness in childhood. Perinatal HCMV infection is also acquired through transfusion and there is even a low residual risk of HCMV transmission by both HCMV-seronegative and WBC-reduced seropositive blood.<sup>57</sup> In a recent study,<sup>58</sup> hepatosplenomegaly was the most common feature in these children. Other symptoms/signs were developmental delay, jaundice, convulsions, pneumonitis, visual and hearing impairment, hydrocephaly, congenital cataract, etc.

## INFECTION IN IMMUNOCOMPETENT ADULTS

Majority of children and adults experience a subclinical infection with HCMV marked only by seroconversion. Sexually active young adults are most often involved and the disease may also follow transfusion of blood products. Incubation period is 20–60 days and the disease generally lasts for 2–6 weeks. Intermittent shedding of virus from the pharynx, genital secretions, urine, or saliva may occur for many months or even years after primary infection. In those who develop clinical symptoms, a self-limited infectious mononucleosis like syndrome is the most frequent manifestation,<sup>59</sup> with few long term sequelae like prolonged fever, myalgia, malaise, and liver function abnormalities. These patients develop atypical lymphocytosis similar to infections with Epstein–Barr virus but without a positive heterophile antibody test. However, severe life-threatening complications of HCMV infection in immunocompetent patients may not be as rare as previously thought. In a recent review of available literature,<sup>60</sup> the gastrointestinal tract (colitis) and the central nervous system (meningitis, encephalitis, transverse myelitis) were found to be the most frequent sites of severe HCMV infection in these individuals. Manifestations from other organ-systems include hematological disorders (hemolytic anemia, thrombocytopenia), thrombosis of the venous or arterial vascular system, ocular

**Box 33.1** Perinatal Transmission of HCMV<sup>52</sup>

involvement (uveitis), and lung disease (pneumonitis). Recently, HCMV infection was found commonly in chronic HBV and HCV patients, who can be regarded as patients at high risk for HCMV disease. Replication of HBV and HCV were inhibited in HCMV-positive cases.<sup>61</sup> The virus has been observed in the female lower genital tract (cervix and vagina) with an incidence of 4% to 12%, as demonstrated by the presence of intracellular inclusion bodies on Papanicolaou smears or at direct biopsy.<sup>62</sup> Painful acute genital ulcers were reported in the context of a primary HCMV infection. HCMV disease should be considered in the screening of acute ulcers/swelling of the vulva.<sup>63,64</sup>

### INFECTION IN IMMUNOCOMPROMISED HOSTS

HCMV infection remains one of the most challenging infections in both solid organ transplant (and hemopoietic stem cell transplant recipients and is also responsible for life-threatening diseases in patients infected with HIV.<sup>65,66</sup> The spectrum of the disease varies, depending on the extent of immunosuppression. Retinitis, in subjects with HIV infection and pneumonia in recipients of transplants, are the main clinical manifestations. When immunosuppression is more severe, extensive overwhelming infections may result and patients may experience mild or severe hepatitis,<sup>66</sup> destructive retinitis, meningoencephalitis, poly radiculopathy, myelopathy, encephalitis, gastrointestinal tract disease, causing ulcers or bleeding, adrenal involvement, myocarditis, and pancreatitis.<sup>66</sup> The maximum period of risk appears from 1 to 4 months after transplantation, although retinitis may appear later. HCMV disease may occur in cancer patients.

### HCMV INFECTION IN AIDS PATIENTS

HCMV infection is extremely common in AIDS, causing retinitis or disseminated disease and may result in death.<sup>66</sup> The risk is directly related to severity of HIV disease, i.e., the degree of immunosuppression, which may be pronounced due to HCMV infection. Infection can be “new” or due to reactivation and severe and/or fatal organ involvement can occur. Retinitis is an important cause of blindness in these patients. Differential diagnosis from other causes of retinopathy, including toxoplasmosis, candidiasis, and HSV infection should be carried out.

## Laboratory Diagnosis

Testing for HCMV is usually not recommended as a part of routine STI screening because of the high rate of infection in the community and because HCMV in normal individuals does not cause much problem. Laboratory diagnosis is usually carried out when patients are having symptoms of suspected HCMV infection. Early diagnosis and the introduction of preemptive antiviral therapy have reduced HCMV-related mortality after allogeneic stem cell transplantation.

The virus is found in body fluids, including urine, saliva, breast milk, blood, tears, semen, and vaginal fluids. The diagnosis of primary symptomatic HCMV infection can be made only

by careful correlation of the clinical illness with the results of laboratory tests. It should be kept in mind that there is a high frequency of asymptomatic shedding of HCMV and appearance of IgM antibody during reactivation of latent virus.

### DIRECT DETECTION METHODS

#### Direct Microscopy of Stained Smear/Tissues Under Papanicolaou/Hematoxylin-Eosin Stain

In cytological examination, HCMV infection cannot be implied unless typical HCMV-infected cells are present. Presence of large cells of 25–35  $\mu$  size containing massive central intranuclear, basophilic inclusion body, separated from nuclear membrane by a halo and resembling “owl’s eye,” is diagnostic (Fig. 33.2).<sup>67</sup> The small intracytoplasmic inclusions are visualized with Wright/Giemsa stain. However, such cells are not always observed in HCMV-infected cases. Sensitivity of the technique is less but it is rapid and more specific than culture.

#### Direct Detection of Antigen

HCMV antigen may be detected in histologic sections, blood collected in an anticoagulant (circulating neutrophils), and bronchoalveolar lavage fluids (BAL). In neonates, urine samples may be used for diagnosis in the first 2 weeks of life. A commercially available HCMV antigenemia assay was found to be a rapid and sensitive method<sup>68</sup> for evaluating transplant patients and HIV-HCMV coinfection. Monoclonal antibodies assist in the rapid diagnosis of HCMV infection in patient specimens as well as in cell culture. In lung biopsy specimens, the sensitivity is high. HCMV antigenemia assay is significantly more sensitive than shell vial cultures for detection of HCMV in the PMNL fraction of blood leukocytes and is recommended as the method of choice for rapid diagnosis of HCMV viremia,<sup>69</sup> specially in renal transplant patients.<sup>70</sup> However, any HCMV antigen assay may not be always useful in an immunosuppressed host as the antigenemia is transient and sensitivity varies from 31.6% to 100%.<sup>68,71</sup> Recently, it was observed that in bone marrow and liver

**Fig. 33.2:** Inclusion of cytomegalovirus in histologic section. *Courtesy:* SJ Wincelous, UK. Reproduced with permission from Schofield JB, Wincelous SJ. Anorectal manifestations of sexually transmitted infections. *Colorectal Dis* 2001;3:74–81.

transplant recipients, an immediate-early (IE) antigenemia assay could replace the pp65 antigenemia assay for early detection and monitoring of active HCMV infection.<sup>72</sup>

### Direct Detection of DNA

DNA and RNA hybridization, RNA amplification, cytohybridization, and polymerase chain reaction (PCR) assays for detection of HCMV DNA are more sensitive than culture and sensitivity is comparable with viral antigen detection techniques.<sup>73,74</sup>

- (i) Murex hybrid capture DNA assay (HCS) is a solution hybridization antibody capture assay for detection and quantitation of HCMV DNA in leukocytes. PCR is more sensitive than HCS, which is more sensitive than the blood culture assay. Although all patients with HCMV disease are correctly identified by HCS, the lower sensitivity limit of the HCS assay may still be insufficient to allow diagnosis of HCMV infection, early enough to prevent HCMV disease in patients.<sup>73</sup>
- (ii) PCR assay detects HCMV DNA in samples other than WBC, e.g., whole blood, plasma, BAL fluid, or cerebrospinal fluid.<sup>75</sup> PCR detection of HCMV DNA is a semiquantitative test and the quantity of HCMV DNAemia as well as pp65 antigenemia have correlated with risk and severity of HCMV disease in immunocompromised patients.<sup>76</sup> There is good association between double primer PCR assay of PMNL and antigenemia assays for detection of active HCMV infection in all patients of bone marrow transplants and the former can be an alternative method for antigenemia assay. Quantitative PCR methods are necessary for monitoring antiviral treatment.<sup>77</sup> Recently, high concordance between COBAS Amplicor HCMV Monitor (CACM) and an in-house PCR assay for the monitoring of HCMV infection was documented.<sup>78</sup>
- (iii) The real-time (RT) PCR assays, using TaqMan probes and molecular beacons to determine viral load in patients' samples compared well with a well-established, validated, gel-based PCR method and these are accurate, rapid, and reliable assays for the diagnosis and monitoring of EBV and HCMV infections.<sup>79</sup> In studies on AIDS patients undergoing liver and/or renal transplant, high peak viral load has been used for prediction of the development of active CMV diseases. With the availability of effective antiviral therapy, one goal of management is prevention of CMV disease through the detection of significant load of CMV DNA before end-organ disease has developed. Antiviral therapy can then be used to lower the CMV DNA levels and prevent the development of end-organ disease. RT PCR assay was found to be more useful than the direct immunoperoxidase (DIP) staining of leukocytes with peroxidase-labeled monoclonal antibody (C7-HRP test) as a rapid diagnostic test for early diagnosis and treatment of HCMV infection. RT PCR was useful for monitoring HCMV infection during treatment

using ganciclovir (GCV). Moreover, it was quicker, simpler, and cheaper than other RT PCR assays.<sup>80</sup>

Recently, the plasma RT-PCR from Abbott was found to be more suitable than the antigenemia assay for monitoring active HCMV infection in allogeneic hematopoietic stem cell transplantation (Allo-SCT) recipients and may be used for guiding preemptive therapy in this clinical setting.<sup>81</sup> The PCR assay tested positive both before the onset of symptoms and during the disease period.

- (iv) Quantitative-competitive DNA-PCR (QC-PCR) in peripheral blood was compared with HCMV pp65 antigenemia assay in leukocyte fraction, viremia, and the nucleic acid sequence-based amplification (NASBA) for detection of HCMV pp67-mRNA. Correlations of the number of pp65-positive cells with the number of HCMV DNA genome copies/mL and also with the pp67 mRNA-positivity were statistically significant.<sup>82</sup>

In HIV-infected patients, virological screening by qualitative assays from blood, urine, and throat swab specimens for detection of HCMV are of limited value for prediction of the development of HCMV disease.<sup>83</sup> A study carried out in AIDS patients proved by autopsy indicated that quantitative HCMV PCR is best used to rule in rather than to rule out HCMV disease in HIV-infected individuals at high risk.<sup>84</sup>

### ISOLATION OF VIRUS

The virus can be isolated from throat washings, urine, saliva, peripheral blood leukocytes, breast milk, biopsy material, infected liver, lung, semen, and cervical secretions.<sup>40</sup> It grows only in human diploid fibroblast cell culture<sup>85</sup> and usually requires 2–4 weeks. The time of development of CPE depends on the concentration of virus in the initial specimen. If the virus titers are high, as in congenital disseminated infection or in patients with AIDS, characteristic CPE may be detected within a few days. Rapid culture techniques have been developed and include:

- (i) **Detection of early antigen fluorescent foci (DEAFF) test** in cell culture is a rapid method of detecting HCMV. Inoculation of the specimens is carried out by centrifuging them in a shell vial with a cover slip, seeded with diploid fibroblast cells. After 16–36 hours of incubation, the cover slip is stained with either an immunofluorescence (IF) or immunoperoxidase (IP) labeled monoclonal antibody against the IE antigen. The DEAFF test and conventional cell culture had 99% concordance but the former gave much more rapid results<sup>86</sup> and is the current test of choice for the diagnosis of HCMV infection. A rapid assay for detection of HCMV in saliva compared well with standard culture, being as sensitive as detection of viruria. It was suitable for screening of newborns for HCMV as saliva can be collected with less difficulty and expense than urine.<sup>87</sup>
- (ii) **Culture amplified enzyme linked immunosorbent assay (EIA)** has also been used for rapid (within 24–

48 hours) detection of HCMV in the lung tissue of immunocompromised patients with life-threatening pneumonitis.<sup>88</sup> To prove the etiology of a suspected HCMV disease, it is important that tissue involvement is documented by the presence of inclusions, antigen, or viral nucleic acid within the cells, in addition to isolation of the virus.<sup>4</sup> Detection of HCMV viremia is a better predictor of acute infection.

## SEROLOGY

The serological tests (evidence of IgM activity, IgG avidity) for HCMV are useful in the immunocompetent host; whereas in the immunocompromised host, cytological detection (demonstration of typical cytological aspects and positive immunohistology for antigens) and/or virological detection (isolation of virus or evidence of viral antigens or viral DNA) are needed.

A battery of serological tests like complement fixation, IF, and EIA are available for detecting antibodies to HCMV.<sup>8</sup> However, rise in antibody level may not be detectable for up to 4 weeks after primary infection and titers may remain high for many years after infection. Therefore, a single serological assay is of limited value in the diagnosis of HCMV infection except in screening of blood or organ donors.

HCMV IgM may be detected during primary infection in infectious mononucleosis patients or in pregnant women but these tests may be nonspecific because of false-positivity. However, immunocompromised patients, having clinically significant HCMV infection, cannot mount an appropriate immune response and may acquire passive antibody due to frequent blood transfusions. Besides, homosexuals have high IgM levels because of repeated infections and reactivation.<sup>1</sup>

### Serological tests:

- (i) Immunoassays that use early antigen (recombinant HCMV CM<sub>2</sub> and p52) are 5 times more sensitive than HCMV EIA assay using viral lysate and are specific in the detection of active HCMV infection.<sup>89</sup>
- (ii) A luciferase immunoprecipitation system (LIPS) provides a highly robust and quantitative method for studying anti-HCMV antibodies and has the potential to document HCMV infection more accurately than standard EIA.<sup>90</sup>
- (iii) Different commercial assays, including Abbott AxSYM, for HCMV-specific IgM antibodies for the detection of recent HCMV infection, were compared. In selected IgM positive samples, an HCMV IgG avidity assay (Radim) and virus isolation from urine (shell vial) were also performed. There are differences in the sensitivity of the commercially available tests for HCMV antibodies.<sup>91</sup>
- (iv) Testing for IgG avidity antibody in pregnant women, positive for IgM antibodies, may increase the reliability of serological tests. An anti HCMV IgG avidity test was performed to exclude recent infection in patients with anti HCMV IgM antibodies, detected during the first trimester

and also on the follow-up, to exclude the risk of congenital infection. A high avidity index during the first trimester of pregnancy may be considered as a good indicator of past infection and invasive prenatal diagnosis is not necessary. Nearly 70% of the IgM-positive women may be reassured if the first serology is systematically performed before 12 weeks of gestation.<sup>92</sup> HCMV screening in pregnancy is performed as a first step by immunoassays and the choice of highly sensitive IgM tests, associated with further serological and virological methods, could help to identify early primary infections.<sup>93</sup>

- (v) A simple and reliable EIA, recently developed to detect antibodies against the polymorphic epitopes within the two envelope glycoproteins of HCMV, i.e., H and B, is useful for the detection of serologic responses to HCMV strains and the identification of HCMV reinfections.<sup>94</sup>

## Treatment

Asymptomatic HCMV patients do not need any treatment. For symptomatic patients, drugs like foscarnet, GCV, and VGCV are effective in treating the infection.<sup>102,103</sup>

### GANCICLOVIR

It is the most commonly used agent for the prevention of HCMV infection and disease in solid organ transplant recipients. It is a nucleoside analog, related to acyclovir but differs from it by a single carboxyl side chain. Because of this change, the drug is much more active than acyclovir against HCMV. The active compound produced in the body is ganciclovir triphosphate and it inhibits HCMV DNA polymerase. It is a virustatic agent, mostly used for serious HCMV disease like retinitis.

GCV is initially administered intravenously (IV) in a dose of 5 mg/kg twice daily for 2–3 weeks, followed by maintenance therapy of 5 mg/kg once daily to prevent or delay relapses. The recommended oral dose is 3 g daily but a higher dose may prove to be more effective, as oral ganciclovir is not absorbed well.<sup>104</sup> A sustained-release intravitreal implant of GCV is available.<sup>105</sup> A randomized study comparing the IV therapy with implant revealed much longer progression time in the group receiving the implant.<sup>106</sup> It has minimal systemic toxicity, while the other routes cause neutropenia, leading to premature discontinuation of treatment. The neutropenia is usually reversible and cytokines such as granulocyte colony stimulating factor help in reversal. GCV is especially toxic in patients on zidovudine. Sometimes it also causes nausea, vomiting, and diarrhea due to gastrointestinal (GI) disturbance and confusion, convulsions, headache and dizziness due to central nervous system (CNS) involvement. HCMV retinitis progresses in spite of active treatment but GCV slows the progression. It may also be useful in 70–90% of HCMV hepatitis and colitis but in only 30–50% of those with pneumonitis.

## GANCICLOVIR-RESISTANT HCMV

As a result of the widespread use of antiviral prophylaxis and preemptive therapy, there is increasing recognition of GCV-resistant HCMV infection. The overall incidence varies widely among transplant groups, with the highest incidence among recipients of lung and combined kidney–pancreas transplants.<sup>107</sup> Resistance has been reported due to impaired phosphorylation.

## FOSCARNET

It is an inorganic pyrophosphate analog and inhibits HCMV DNA polymerase without requiring intracellular phosphorylation as in the case of GCV. As mentioned previously, impaired phosphorylation is the mode of development of resistance to GCV and foscarnet may be used to treat patients with GCV-resistant HCMV strains. It is used as an alternative therapy for HCMV retinitis at a dose of 60 mg/kg IV, thrice daily for 2–3 weeks, followed by maintenance therapy of 120 mg/kg daily.<sup>107</sup> Efficacy of GCV and foscarnet in clinical trials has been found to be equivalent in treating retinitis.<sup>108</sup> A larger survival time was reported with foscarnet, probably because some of the patients were not able to tolerate concurrent GCV and anti-retroviral drugs because of increased myelosuppression. Moreover, foscarnet has intrinsic anti-retroviral activity. It is also useful in the treatment of HCMV GI disease. As excretion of foscarnet is entirely renal, it can cause renal toxicity, serum electrolyte imbalance, anemia, and neurotoxicity. Adequate hydration of patients with saline may reduce nephrotoxicity.<sup>8</sup> However, resistance to foscarnet can occur due to mutations in DNA polymerase. Combination of GCV and foscarnet is more effective in the treatment of refractory diseases.<sup>109</sup>

## CIDOFOVIR

It is active against majority of GCV-resistant viruses,<sup>110</sup> and may be administered at long intervals as maintenance dose, as it has got a long half-life. During therapy, the renal functions should be monitored, as the drug is nephrotoxic.

## VALGANCICLOVIR (VGCV)

It is an oral prodrug valyl derivative of GCV, with a 10-fold greater bioavailability than oral GCV. After absorption through the gut, the valine moiety is rapidly cleaved off by the liver, yielding GCV. The active drug is a guanosine analog that inhibits viral (and cellular) DNA synthesis by chain termination. Studies of VGCV among HIV-infected HCMV-seropositive patients and liver transplant recipients suggest that it has the potential to replace both oral and IV GCV in many situations.<sup>111</sup>

VGCV is administered orally and the recommended induction dosage is two tablets (800 mg) taken twice daily with food for 21 days; food increases bioavailability. The maintenance dosage is two tablets taken once daily with food. In liver-transplant patients and in patients with AIDS, this dosage gives maximum

serum concentrations and 24-hour total drug exposure equivalent to 5 mg/kg IV GCV twice daily and far greater concentrations than those achieved by the daily oral dosage of GCV. Because VGCV is excreted primarily through the kidneys, dosage must be decreased in patients with impaired renal function.<sup>112</sup> Oral VGCV is as effective as comparable doses of IV GCV in stopping progression of newly diagnosed HCMV retinitis.

Viruses resistant to GCV can be selected after prolonged treatment with VGCV. Initial resistance has also been noted in patients previously untreated with GCV. VGCV is highly effective for prophylaxis of HCMV reactivation in patients receiving alemtuzumab, an immunosuppressive antibody that destroys T and B cells.<sup>113</sup>

## Prevention

HCMV infection can be prevented in patients at high risk by screening of blood for HCMV antibodies before blood transfusion or organ transplantation and also using frozen thawed and deglycerolized blood. Component processing, leukocyte reduction, and platelet apheresis in normal blood and platelet donors reduce HCMV viral load quantified by PCR and were found to be effective in preventing transmission of HCMV infection.<sup>95</sup> Maintenance of strict hygiene, including hand washing and wearing of gloves while dealing with young children shedding HCMV, have been recommended.<sup>96</sup> In hospitals, standard precautions were found to be effective in preventing spread from infected patients to healthcare workers.<sup>97</sup> As HCMV in human breast milk poses risk to the premature infant,<sup>98</sup> milk from seropositive donors should not be provided to seronegative newborns. HCMV is commonly secreted in semen; therefore, HCMV antibodies should be screened in semen donors before artificial insemination.<sup>99</sup>

## CHEMOPROPHYLAXIS

Prophylactic acyclovir was found to reduce HCMV infections and disease in seronegative renal transplant recipients.<sup>8</sup> Alternate day ganciclovir/ foscarnet for HCMV prophylaxis in “at risk” allogeneic stem cell transplant related and unrelated recipients is 100% effective in preventing HCMV infections.<sup>100</sup> Oral valganciclovir (VGCV) facilitated treatment compliance without being inferior to other prophylactic therapies. However, it failed to provide adequate prophylaxis following liver transplantation.<sup>101</sup>

## HCMV VACCINE

Although several trials in humans are running at present, no successful vaccine is available to prevent HCMV infection. HCMV immunoglobulin prepared from sera of high titered donors has been reported to reduce HCMV associated syndromes and to prevent infections in renal and bone marrow transplant recipients but the results are not always favorable.

### Summary

Human cytomegaloviruses (HCMVs) are ubiquitous large DNA viruses grouped under herpes viruses producing a variety of human infections in all age groups. Like all herpes viruses, it establishes a lifelong latent infection once it enters a person's body, and there is potential for reactivation and recurrent illness in immune-suppressed patients such as in post transplant cases or in HIV infected patients.

The common mode of transmission of the virus is either through sexual route by exchange of semen, vaginal fluid or saliva, or nonsexual routes like respiratory, through blood transfusion, sharing needles, organ transplantation, and perinatal. Sexual transmission occurs in heterosexuals, men who have sex with men (MSM), and women who have sex with women.

Incubation period is 20–60 days, and the disease generally lasts for 2–6 weeks in majority of immune competent children and adults. It is a widespread opportunistic pathogen that causes no obvious clinical manifestation in healthy individuals, but poses an important public health problem because of the high frequency of congenital infections resulting in serious birth defects. Infections acquired after birth are generally mild and range from asymptomatic subclinical infection to a mononucleosis-like syndrome in normal individuals but may be fatal in immune-compromised patients. HCMV infection remains one of the most challenging infectious complications in both solid organ transplant and hemopoietic stem cell transplant recipients and is also responsible for life-threatening diseases in patients infected with HIV.

Testing is usually not recommended as a part of routine STI screening because of the high rate of infection in the community and because the virus does not cause much problem in normal individuals. Laboratory diagnostic procedures are usually carried out when patients are having symptoms of suspected HCMV infection, especially in allogeneic stem cell recipients. The diagnosis of primary symptomatic HCMV infection can be made only by careful correlation of the clinical illness with the results of laboratory tests. It should be kept in mind that there is a high frequency of asymptomatic shedding of virus and appearance of IgM antibody during reactivation of latent virus. Different direct detection methods are available like direct microscopy of stained smear/tissues to detect typical HCMV-infected cells, HCMV antigenemia assay, a rapid and sensitive method for evaluating transplant patients and HIV-HCMV coinfection, and different methods for direct detection of DNA. The virus can be isolated from throat washings, urine, saliva, peripheral blood leukocytes, breast milk, biopsy material, infected liver, lung, semen, and cervical secretions in human diploid fibroblast cell culture. In AIDS patients undergoing liver and/or renal transplant, high peak viral load has been used for prediction of the development of active HCMV diseases. The serological tests (evidence of IgM activity, IgG avidity) are useful only in the immune-competent host. However, rise in antibody level may not be detectable for up to 4 weeks after primary infection, and titers may remain high for many years after infection. Therefore, a single serological assay is of limited value in the diagnosis of this infection except in screening of blood or organ donors. A simple and reliable EIA, recently developed to detect antibodies against the polymorphic epitopes within the two envelope glycoproteins of HCMV, i.e., H and B, is useful for the detection of serologic responses to different strains and the identification of re-infection.

Asymptomatic patients do not need any treatment. For symptomatic patients, drugs like foscarnet, gancyclovir (GCV), and valgancyclovir are effective. Foscarnet may be used to treat patients with GCV-resistant HCMV strains.

# Epstein–Barr Virus Infections

Raj Patel

# 34

## Introduction

The gamma herpes subfamily is characterized by their ability to establish latent infection of lymphocytes. By looking at gene structure and products, members of the family are further grouped into the *lymphocryptovirus* and *rhadinovirus* genera. Both these groups contain important pathogens implicated in acute and chronic human diseases and cause significant morbidity in immunocompromised individuals. In addition, these viruses are implicated in oncogenesis. The *rhadinovirus* group contains human herpes virus 8 (Kaposi sarcoma herpes virus KSHV). Epstein–Barr virus (EBV) is a member of the *lymphocryptovirus* group. Both these viruses may be transmitted sexually. This chapter will describe the biology and features of EBV disease pertinent to an adult STI/HIV or dermatology practice.

## Epidemiology

Infection with EBV is followed by the development of permanent EBV-specific antibody. Seroepidemiological studies of antibody to EBV show that detectable levels in the range of 90–95% are encountered in most populations from both developed and developing countries.<sup>1</sup> The majority of infections tend to occur in childhood, and over 50% of infections do occur by the age of 5 years. Infections early in life tend to be asymptomatic. With economic development, infections are increasingly seen in later life; however, even then, cases beyond the third decade of life are rarely seen.<sup>2,3</sup> When the infection is delayed to adolescence and adult life, the clinical syndrome of acute infectious mononucleosis (IM) occurs.

## Biology

EBV has two target tissues: (i) B-lymphocytes where infection is essentially non-productive and is the site of latency and (ii) stratified squamous epithelium such as that found in the pharynx and genital areas in which replication occurs. Primary infection typically occurs through the inoculation of EBV in infectious saliva (also known as “kissing disease”) onto stratified epithelium.

Transmission through the receipt of blood and other tissues has also been described.<sup>4</sup> Productive replication ensues with the infection of oropharyngeal mucosa. B-lymphocytes close to the site of infection become infected, and infection spreads via the circulation. Approximately one-third of adults develop the clinical syndrome of IM.

## LATENT INFECTION

EBV establishes latency within the B-lymphocytes. The DNA circularizes to form an episome.<sup>5</sup> Restricted gene expression allows the infected cell to evade immune surveillance. During latency, only one in 10 lymphocytes is infected. Clinical reactivation can recur but is an infrequent event in an immunocompetent individual. Subclinical reactivation and viral shedding do occur from both the genital and pharyngeal mucosal surfaces. Virus can be recovered from saliva in up to 20–33% of healthy individuals at any one time and in over 90% with follow-up over a year.<sup>6–8</sup> Rates are higher in the immunocompromised. Debate persists as to the origins of such reactivated virus. Recent data suggest that this virus results from re-infection of mucosa from reactivating virus in B-lymphocytes.<sup>9</sup> True chronic productive infection of the oropharyngeal mucosa has been described (oral hairy leukoplakia), but this is a relatively rare phenomenon and not seen in the immunocompetent.

## GENE EXPRESSION DURING DIFFERENT STAGES OF INFECTION

The infectious virus particle consists of a nucleocapsid containing double-stranded linear DNA. The viral genome of 172 kb has been fully characterized and is known to contain 90 genes. Infectious virions are produced during the lytic stage of the infection when a wide range of gene products can be detected.

During latency, 11 genes are differentially expressed: six gene codes for nuclear proteins (EBNA1–6), three codes for membrane proteins (LMP1, LMP2a, and LMP2b), and two codes for small RNA molecules, the EBV-encoded RNAs (EBERs). Of these, LMP1 and EBNA 1, 2, 3, 5, and 6 are essential for the transforming capacity of the virus. Patterns in the epidemiology

of EBV-related malignancies have been linked to differences in viral protein expression during latency.

### SEROLOGICAL CHANGES

A characteristic antibody response develops after primary infection with antibodies to viral capsid antigen (VCA) and the early antigens (EAs), followed in several weeks or months by antibodies to EBV nuclear antigen (EBNA).<sup>10</sup> The ability of EBV to maintain lifelong infection following primary infection with low levels of replication and viral shedding and enduring antigen exposure results in continued humoral immune response with lifelong antibodies to VCA and EBNA and low levels of antibodies to the EA complex that may only be intermittently detectable in 10–20% of individuals. Different serological markers and their interpretations are given in Table 34.1.

### STRAIN DIFFERENTIATION AND CO-INFECTION

EBV isolates can be categorized into two types, EBV-1 and EBV-2, based on gene polymorphism for EBNA2 (specifically EBNA2, 3A, 3B, and 3C).<sup>11–13</sup> EBV-1 and EBV-2 have biologic differences many of which are accounted for by differences in EBNA2. Type-1 and type-2 strains differ in their ability to transform B-lymphocytes in culture.<sup>14,15</sup> EBNA polymorphisms generate immunological responses that are both type-specific and cross-reactive. Responses to EBNA2 and 3A are partially cross-reactive between the two types. The antibody responses to EBNA3B and 3C are essentially type-specific.<sup>16,17</sup> Similarly, both cross-reactive and type-specific T-cell responses can be detected.

EBV-1 and EBV-2 are distributed widely geographically.<sup>18–20</sup> Infection with one type does not protect against subsequent infection by another type. Co-infection with EBV-1 and EBV-2 is reported in 9–27% of populations and appears to be higher in STI clinic attendees. In addition, distinct subvirus populations have been identified from separate anatomical sites in patients suggesting that oral and genital exposures may result in different infections. Neither EBV type shows anatomical site specificity.

### CLINICAL FEATURES

Primary EBV infection may be seen as a benign lymphoproliferative disorder. The characteristic features are the gradual onsets of sore

**Table 34.2:** Clinical Signs/Symptoms and Laboratory Investigations in Infectious Mononucleosis

Clinical sign/symptom	Percentage
Lymphadenopathy	97
Pharyngotonsillitis	77
Fever	81
Splenomegaly	56
Hepatomegaly	13
Jaundice	7
Myocarditis	3
Meningoencephalitis	<1
Genital ulcers	<1
Laboratory test	Percentage
Elevated transaminases (>40 IU)	85
Neutropenia (<3000 cells/ $\mu$ L)	70
Lymphocytosis (>50% lymphocytes)	70
Thrombocytopenia	20
Hemolytic anemia	4

throat, fever, and lymphadenopathy. Diagnostic clinical and laboratory criteria are given in Table 34.2. This disseminated infection can involve almost any system. Most symptoms resolve within 4 weeks.<sup>21</sup>

Occasionally, IM may be confused with symptomatic primary HIV-1 infection. However, the presence of hepatosplenomegaly and heterophil antibody is a useful differentiating point. However, it is advisable that when HIV does enter the differential diagnosis, the laboratory confirmation of EBV infection is a must. If tests for EBV such as heterophil and VCA immunoglobulin M (IgM) antibody tests are negative, then tests for early HIV infection should be conducted (HIV RNA reverse transcriptase-polymerase chain reaction or proviral DNA detection with HIV p24 antigen tests).<sup>22</sup>

Young children rarely develop symptoms. Symptoms, if present, are similar to those found in adults although pharyngitis and lymphadenopathy tend to predominate.

Serious fatal complications are rare and estimated to be less than one case per 3000.<sup>21</sup> Deaths occur predominantly in patients with immunodeficiency who present atypically. Severe tonsillar enlargement resulting in respiratory obstruction, pneumonitis, splenic rupture, neurological involvement, liver failure, and myocarditis have been described in previous studies.<sup>23</sup>

Patients, if admitted to hospital with IM, do not require isolation conditions.

### Diagnosis and Management of Primary EBV Infection

The heterophil (Paul-Bunnell) antibody test is positive in most (>90%) of patients over the age of 10 with IM.<sup>24</sup> However, in younger children it is unreliable and it is then necessary to perform specific EBV serology.

Much is now known concerning the immunopathology of IM. The severity of acute symptoms in IM is related to the extent of immune activation and is predominantly mediated by this

**Table 34.1:** Interpretation of Epstein–Barr Virus Serology Test Results

Clinical situation	Heterophile antibody	IgG-VCA	IgM-VCA	EA	EBNA
No past infection	Usually –	–	–	–	–
Acute infection	Usually +	+	+	+	–
Convalescent phase	+/-	+	+ or –	+ or –	+
Past infection	Usually –	+	–	– or W+	+
Chronic or reactivation	Not useful	+	–	+	+

EA, early antigen; EBNA, Epstein–Barr nuclear antigen; VCA, viral capsid antigen; W+, weakly positive.

mechanism.<sup>22</sup> Symptoms appear to be associated with an excessive burst of cytokines induced by virus-mediated polyclonal B-cell activation resulting in immunogenic B-lymphocytes. Patients lacking both EBV-induced IFN- $\gamma$  and perforin-positive, CD8-positive T-cells have generally been found to develop disseminated infection proceeding to long-lasting lymphoproliferative disorders. In the usual situation, the development of the CD8-positive T-cell immune response is followed by the rapid decline in number of EBV-infected B-cells, going from 1–30% at the height of IM to less than 0.0002%.<sup>25</sup>

### Treatment of Infectious Mononucleosis

Numerous trials of antivirals and immune modulators have been conducted. Generally, the use of antivirals has demonstrated no significant effect on IM-associated symptoms despite good evidence of significant antiviral effects.<sup>26–28</sup> This is not surprising since most of the symptoms of IM are considered to be due to immune mechanisms and not the direct consequence of viral replication.

However, despite these findings it is still advisable to treat EBV-related life-threatening complications including autoimmune thrombocytopenia, hemolytic anemia, fulminant hepatitis and meningoencephalitis with convulsions.<sup>22</sup>

Although trials of steroids with antivirals have shown no reduction in signs or symptoms related to IM, they may still be indicated in some situations. Steroids may be helpful in reducing swelling and reducing obstructive symptoms and are helpful in managing thrombocytopenia.<sup>27</sup> Intravenous IgG has also been used in thrombocytopenia and shows a much more rapid effect.<sup>29</sup> Plasmapheresis combined with pooled human IgG has also been shown to be effective in cholestatic hepatitis, thrombocytopenia, and disseminated intravascular coagulation.

Interstitial pneumonitis complicating IM may be treated with a combination of subcutaneous IFN- $\gamma$  with oral steroids and acyclovir. Low-dose serotonin blockade (citalopram) has been used in post-infectious asthenia and in open studies shows a 50% response.<sup>30</sup>

### Primary EBV Infection in the Immunocompromised State

Patients with acquired or congenital immunodeficiency may develop hemophagocytic syndrome, agammaglobulinemia, aplastic anemia, or lymphoma after IM.<sup>31,32</sup> In these cases, serological markers of EBV may be lacking, and the diagnosis has to be based on EBV DNA detection by PCR.

Fatal IM has been described in familial clusters occurring in boys inheriting this susceptibility in an X-linked pattern.<sup>33,34</sup> The syndrome is characterized by the persistence of IM-like symptoms that eventually develop into aplastic anemia, lymphoproliferative disorder, or lymphoma. It is fatal in 75% of the cases. Once diagnosed in a family, prophylactic antivirals with bone marrow transplant of other susceptible members can be completely protective.<sup>35</sup>

### Genital EBV Infection

Many lines of evidence indicate that genital epithelium can be infected by EBV and subsequently can shed EBV intermittently. The B-lymphocyte receptor for EBV, C3d, has been found on genital epithelial cells.<sup>36</sup> Cell-free EBV can be detected in cervical washings, and EBV DNA can be detected by in-situ cytohybridization. PCR has detected EBV DNA in uterine cervix, urethra, vulva, and anal mucosa. EBV can also be found in infected discharges.<sup>37–42</sup> It is however, unknown as to whether genital EBV is primarily contracted sexually and as to whether genital EBV is infectious to partners.

An important issue has been to investigate if the presence of genital EBV could be related to specific micromorphological patterns in the genital epithelium. In a study, EBV was demonstrated to be present in 47% of women with acetowhite koilocytotic lesions of the vulva compared to 11% of the controls.<sup>40</sup> However, care needs to be exercised in the interpretation of results such as these. Acetowhite changes are non-specific<sup>43</sup> and may indicate an area of inflammatory change where B-lymphocytes carrying EBV are especially found. Future studies using in-situ hybridization may resolve this issue.

There are a number of reports in the literature concerning genitals ulcers in patients with IM.<sup>44–47</sup> These cases document the development of acute labial ulcers associated with symptoms and signs of classical IM. Ulcers tend to be deep and characteristically have purple–blue edges. It is highly likely that these lesions are under-reported, and EBV should enter the differential diagnosis of new genital ulcers especially if other more common causes have been excluded.

### EBV Infection in Pregnancy

Symptomatic congenital EBV infection is rare and most likely influenced by the low proportion of women of childbearing age who are susceptible to primary EBV infection during pregnancy and the low pathogenicity of EBV for fetal infection.<sup>48–53</sup> Cases of IM in pregnancy have been reported and followed prospectively showing little apparent risk of fetal involvement. A few cases have been reported with adverse fetal outcome—however, these reports do not conclusively corroborate EBV as the cause of these anomalies.<sup>54–57</sup> Very rare cases of symptomatic congenital EBV have been virologically confirmed, but there is no specific pattern of malformations.<sup>58</sup> The likelihood following either primary or reactivated EBV infection during pregnancy is for a normal outcome.

### EBV INFECTION IN THE IMMUNOCOMPROMISED STATE

The immunocompromised state disrupts the balance between host and EBV. There is an increased risk of reactivation and re-infection with a co-infecting strain. Lack of immune control results in elevated levels of EBV both in peripheral sites as well as the blood.<sup>59–61</sup> Some episodes of reactivation may be associated

with clinical symptoms. Seroepidemiological studies show that most EBV-related malignancies are preceded by a period of enhanced viral activity.<sup>62–64</sup> That such conditions are seen in such high frequency among the immunocompromised may be a consequence of the high burden of EBV that these patients carry.

A number of conditions have now been linked to EBV in the immunocompromised host: polyclonal B-cell proliferation, opportunistic lymphoma, necrotizing hepatitis, uveitis, bronchiolitis obliterans, genital ulcers, and hairy leukoplakia.<sup>65,66</sup>

EBV or part of the EBV genome has also been detected in a variety of neoplastic diseases including African Burkitt lymphoma, nasopharyngeal carcinoma, gastric carcinoma, and leiomyosarcoma.<sup>67</sup> It still remains to be seen whether EBV is a direct cofactor in the genesis of these tumors or an innocent passenger in activated proliferative cells.

### ORAL HAIRY LEUKOPLAKIA

Oral hairy leukoplakia is the only known pathologic manifestation of replicative EBV infection.<sup>68</sup> It is due to EBV-induced cellular proliferation in mucocutaneous cells. It occurs in up to a quarter of HIV-positive homosexual men with AIDS and is also seen in other states of advanced immunosuppression. Rarely it has been reported in healthy individuals.<sup>68,69</sup>

Lesions appear as well-demarcated keratotic areas with a “hairy” or corrugated appearance. Lesions are usually only a few millimeters in size but can be extensive involving large areas of the lingual and oral surfaces. Histological examination will show thickening of the epithelium with characteristic balloon cells resembling koilocytes. Hyperkeratosis results in microscopic hair-like projections on the surface. Viral particles can be seen on electron microscopy. These lesions are rarely symptomatic, although a variety of symptoms have been described including pain. Malignant transformation has not been described, and lesions will usually regress if the underlying immunosuppression can be improved. Lesions do respond to acyclovir therapy.

### EBV-Associated Malignancies in AIDS

A number of malignancies that are related to EBV are seen in significantly higher frequency in the AIDS population. Non-Hodgkin lymphoma (NHL) is 60 times more common in AIDS.<sup>70</sup> NHL can be morphologically divided into Burkitt-like and immunoblastic lymphomas, both of which have a higher association with EBV in AIDS than in the non-AIDS population.<sup>65,66,71</sup> EBV-1 and EBV-2 are both equally associated, reflecting the high prevalence of both these viruses within the HIV population. Burkitt lymphoma appears early in the course of AIDS and is usually not associated with profound immunosuppression. Immunoblastic lymphomas are seen much later in the disease course and usually when cellular immunity is severely disrupted. Immunoblastic lymphomas express latent viral proteins LMP1 and EBNA2 that would normally provide adequate targets for immune control via EBV-specific cytotoxic T-cells.

Within the general population, the association of Hodgkin disease with EBV depends upon the exact histological types. Mixed cellularity and lymphocyte-depleted subtypes are most closely related to EBV, and it is these types that are most often seen in AIDS. Up to 90% of AIDS-related Hodgkin disease is EBV related.<sup>72,73</sup>

Some malignancies not associated with EBV within the general population are found to consistently contain EBV within the HIV-positive population. Both leiomyosarcoma and primary central nervous lymphoma have been shown by in-situ hybridization to contain EBV in AIDS patients.<sup>74</sup>

Using low-dose hydroxy urea has shown to be effective in three patients with EBV-associated primary central nervous system lymphoma in a study.<sup>75</sup> Cidofovir, the acyclic nucleoside phosphonate analog, has shown an antitumor effect against EBV-transformed epithelial cells and lymphocytes in animal studies.<sup>76</sup>

### Future Developments

Significance of EBV-related malignancies has led to considerable efforts to develop effective prophylactic and therapeutic vaccines. Subunit vaccines are actively being explored.

#### Summary

Discovered in 1964, the Epstein–Barr virus (EBV) is widespread in all regions of the world infecting over 95% of the adult population. After initial exposure, EBV establishes a latent infection that persists for the life of the host. It was shown to be the causal agent of infectious mononucleosis in 1970 and since then has been linked to several other clinical syndromes. EBV has been implicated as an etiologic agent in Burkitt lymphoma, post-transplant lymphoproliferative disorders and lymphoma in HIV-infected individuals. Despite obvious epidemiologic implications of a genital distribution of EBV, evidence for direct sexual transmission is lacking. EBV targeted therapies for EBV-positive tumors have shown promise in certain patient groups. Prophylactic and therapeutic vaccines are under evaluation.

# Kaposi Sarcoma Herpesvirus

Rebecca Robey • Mark Bower

## Introduction

Kaposi sarcoma-associated herpesvirus (KSHV), which is also known as human herpesvirus 8 (HHV-8), is an oncogenic gammaherpesvirus that is the etiological agent of Kaposi sarcoma (KS), a mesenchymal tumor characterized by *de novo* vascular formation and lymphocyte infiltration. KSHV is also involved in the pathogenesis of two lymphoproliferative disorders, primary effusion lymphoma (PEL) and multicentric Castleman disease (MCD). As early as the 1960s, the uneven geographical distribution led to the speculation that KS was caused by an infectious agent.<sup>1</sup> This suspicion was compounded by the dramatic rise in KS incidence among immunosuppressed individuals (acquired or iatrogenic) in the 1980s.<sup>2</sup> Moreover, the very high prevalence of KS among people with acquired immune deficiency syndrome (AIDS) pointed towards a sexually-transmitted agent. KS occurs predominantly among homosexual men with human immunodeficiency virus (HIV), with a lower incidence in those who acquired HIV through heterosexual contact and a still lower incidence among those with parenterally-acquired HIV, for example, intravenous drug users and hemophiliacs.<sup>3</sup>

In 1994, Chang et al. identified novel herpesvirus DNA sequences from KS lesions in AIDS patients.<sup>4</sup> Molecular and serological epidemiology studies confirmed that this new herpesvirus (the eighth to be discovered, hence human herpesvirus 8) was present in individuals with all forms of KS, but was not ubiquitous in the general population.<sup>5-7</sup> Furthermore, high levels of HHV8 DNA in the peripheral blood of AIDS patients predicted subsequent development of KS.<sup>8,9</sup> PCR *in situ* hybridization showed that HHV8 was present in endothelial cells and spindle (tumor) cells of KS lesions from all epidemiological forms of KS,<sup>10</sup> and so the virus rapidly became known as KS-associated herpesvirus (KSHV). The observation that KSHV is latently expressed in more than 90% of tumor cells in advanced KS lesions<sup>11</sup> provided further evidence that KSHV was indeed causally-related to KS.

## Molecular Virology of KSHV

KSHV belongs to the lymphotropic herpesvirus subfamily, *gammaherpesviridae*. It is most closely related to the human gamma-1 herpesvirus, Epstein-Barr virus (EBV) or human herpesvirus 4 (HHV4). Like EBV, KSHV establishes latent infection in B cells.<sup>12</sup> However, it has an unusually wide cellular tropism, and has been detected *in vivo* in endothelial cells,<sup>10</sup> epithelial cells,<sup>13</sup> macrophages, and monocytes.<sup>14</sup>

KSHV is a large double-stranded DNA virus. The KSHV genome is approximately 165kb long, with a continuous 145kb-long unique coding region flanked by multiple GC-rich terminal repeat units approximately 800bp in length.<sup>15</sup> Over 90 open reading frames (ORFs) have been identified within the KSHV genome, of which at least 81 ORFs are over 100 amino acids long. The genome consists of seven highly-conserved gene blocks separated by short regions of unique or subfamily-specific genes. The conserved genes have homologs among other herpesviruses and include genes that code for structural proteins and genes involved in viral DNA replication and regulation of gene expression. A large number of the viral genes (both conserved and unique) encode homologs of cellular genes that have been captured from the host during the course of the virus's evolution.<sup>16</sup>

KSHV has developed several complex strategies for subverting the host's adaptive and innate immune system. Approximately one quarter of KSHV genes—both cellular homologs and unique viral genes—are involved in immune evasion. The roles of many viral genes in driving oncogenesis have also now been elucidated and, in many cases, these oncogenic activities result from the same molecular pathways employed by the virus in its immune-evasion activities.<sup>17</sup> The list of cellular processes modulated by KSHV viral genes includes the cell cycle, apoptosis, cytokine production, antigen presentation, cell signaling, and signal transduction. Thus, KSHV infection can result in aberrant cell growth, proliferation, inflammation, and angiogenesis, all of which contribute towards tumor development.

The KSHV ORFs are differentially expressed during the course of the virus's life cycle. During latent infection, the virus exists in

the nucleus as a closed circular episome and very few viral genes are expressed. During the lytic phase of the virus's life cycle, which is the replication phase, the virus linearises and most viral genes are expressed in a temporally-regulated fashion.<sup>18,19</sup> The constitutively-expressed latent genes and lytically-induced genes are referred to as class I and class III transcription units, respectively. Genes displaying a third pattern of gene expression, designated class II transcription, are expressed at low levels during latency but are also induced during lytic replication. Lytic genes are induced sequentially and can be further classified as immediate-early, early or late genes based on the timing of their appearance during replication. The chronological expression of lytic genes correlates with their function. Genes involved in transcription regulation are induced first, followed by those involved in DNA replication and repair, and genes that are involved in virus assembly or code for structural proteins are induced last. Viral homologs of cellular genes involved in immune evasion are predominately immediate-early or early genes, in keeping with their function to prevent the virus from attracting immune surveillance as it replicates in preparation for shedding of virions.<sup>20</sup>

Latent infection itself is, arguably, the primary strategy in immune evasion, as the highly-restricted pattern of viral gene expression that defines latency minimizes the number of viral epitopes that are presented by infected cells to the circulating cells of the immune system. Latency is also the state assumed to lead to clonal proliferation of KSHV-infected cells, since lytic replication results in cell death and is therefore anti-tumorigenic (as the host cell is lysed to release active virions). The vast majority of tumor cells in KS and PEL are latently infected, with only a few cells undergoing lytic replication. Tumor cells from MCD, by contrast, express both latent and lytic proteins.<sup>21,22</sup> Although latent infection is a characteristic of all herpesviruses, the latency genes themselves are not conserved between members of the family, but rather are highly evolved to adapt to their specific host cell environment. The function of the better described genes of KSHV is shown in Table 35.1.

**Table 35.1:** Table of the Better Characterized KSHV Genes

KSHV ORF	Gene product	Function(s)
<b>Latent</b>		
ORF 71	vFLIP	Antiapoptotic
ORF 72	vCyclin	Homolog of cellular cyclin D
ORF 73	LANA-1	Maintenance of the episome, gene expression Immune evasion—inhibition of antigen presentation
<b>Expressed at low-levels in latency and induced during lytic cycle</b>		
K11.1	vIRF-2	Immune evasion—disruption of host antiviral interferon response
K12	Kaposin	Oncogenic, promotes cell proliferation
K15-P	LAMP	Immune evasion—down regulates B-cell receptor signal transduction Activates NFκB, ERK2, and JNK1 pathways
<b>Immediate-early</b>		
ORF 50	Rta	Gene expression—transactivator of lytic replication; both necessary and sufficient for lytic cycle induction

KSHV ORF	Gene product	Function(s)
K8	Zta or K-bZIP	Gene expression—transactivation
ORF 57	KS-SM	Gene expression—post-transcriptional regulation
ORF 9		DNA replication—viral DNA polymerase
ORF 6	SSB	DNA replication—single strand DNA binding protein
ORF 16	vBcl-2	Antiapoptotic—inhibits BAX-mediated and virus-induced apoptosis
K7	vIAP	Antiapoptotic—protects against apoptosis induced by various stimuli
K2	vIL-6	Binds gp130 directly to activate the JAK/STAT signaling pathway Antiapoptotic—inhibits IFN-mediated apoptosis Immune evasion—inhibition of chemokine-driven recruitment of neutrophils
K6	vCCL-1	Immune evasion—skewing of CD4+ T cell response to Th2-type (less effective against intracellular pathogens)
K4	vCCL-2	
K5	MIR2	Immune evasion—downregulates expression of MHC-I, CD86, ICAM1, PECAM1, and CD1d
K14	vCD200 or vOX2	Immune evasion—inhibits myeloid cell activation, reduces production of Th1-attracting cytokines, inhibits neutrophil function
ORF 45		Immune evasion—disruption of host antiviral interferon response by interfering with IRF-7 activity
ORF 74	vGPCR	Binds IL-8; constitutively active GPCR
ORF 58		
Early		
ORF 59	PF8 or PPF	DNA replication—processivity factor, needed for efficient extension by the viral DNA polymerase
ORF 61		DNA replication—large ribonucleotide reductase
K4.1	vCCL-3	Immune evasion—skewing of CD4+ T cell response to Th2-type
K3	MIR1	Immune evasion—downregulates expression of MHC-I and CD1d
K9	vIRF-1	Immune evasion—disruption of host antiviral interferon response; downregulates MHC-I
ORF 4	CBP or KCP	Immune evasion—inhibition of complement
ORF 49		Activates the JNK and p38 MAP kinase pathways
ORF 8	gB	Structural—glycoprotein B
ORF 65		Structural—capsid-interacting protein
Late		
K1		Immune evasion—downregulates B-cell receptor surface expression
ORF 28		
ORF 33		
ORF 36		Activates the c-Jun N-terminal kinase (JNK) pathway
ORF 37	SOX	Immune evasion—host mRNA shut off
K8.1	gp35/37	Structural—glycoprotein 35/37
ORF 22	gH	Structural—glycoprotein H
ORF 25		Structural—major capsid protein
ORF 26		Structural—minor capsid protein

## Epidemiology and Transmission

A serological study by Gao et al. found no evidence of KSHV infection in healthy US blood donors, whereas they observed intermediate to high seroprevalence of KSHV among control populations from Italy (4%) and Uganda (51%)—two countries where KS is endemic.<sup>5</sup> Lennette et al. reported a similar pattern of KSHV seroprevalence, with dramatically higher incidence in the general population of Africa compared to the US, although the actual rates they observed were much higher than the previous study (80% in Uganda and between 4% and 28% in the US depending on the age of the individual).<sup>23</sup> These, and further studies into the epidemiology of KSHV infection, revealed that KSHV is a necessary but not sufficient factor in KS pathogenesis, with immunosuppression representing another important cofactor.

The exact mode of transmission of KSHV is not known. In the West, evidence points towards sexual transmission, with homosexual men having the highest risk of contracting the virus.<sup>24</sup> KSHV has been detected in semen<sup>25</sup> and risk of infection correlates with the number of sexual partners.<sup>26</sup> However, the route of conduction between sexual partners is not known. An extensive study by Dukers et al. into the risk factors for contraction of KSHV among homosexual men found that orogenital sex was significantly associated with KSHV seroconversion, and that this practice was more important than the number of sexual partners.<sup>27</sup> KSHV DNA is readily detectable in saliva and nasal secretions, and cell-free saliva fluid has been demonstrated to infect cell lines *in vitro*.<sup>28–30</sup> Together, this implicates the oropharynx as a possible site of KSHV replication and indicates a role for saliva in KSHV transmission. This is in keeping with the mode of transmission of Epstein-Barr virus, the most-closely related human herpesvirus to KSHV,<sup>31</sup> but has not been definitively confirmed.

By contrast, within African populations seroepidemiological studies point towards horizontal, nonsexual transmission of KSHV, with seroconversion frequently occurring before puberty and seroprevalence increasing linearly with age.<sup>32–36</sup> As with transmission between sexual partners, oral routes of transmission have been suggested and would explain both mother-to-child and sibling-to-sibling transmission. Alternatively, high mother-to-child transmission rates<sup>37</sup> could indicate a role for breast milk, although there is as yet no evidence to support this.

## Kaposi Sarcoma

KS is named after Moritz Kaposi, an Austro-Hungarian dermatologist who first described the disease. In 1872, Kaposi published the case histories of 5 patients suffering from what he described as “idiopathic multiple pigmented sarcomas” of the skin. This form of the disease is now known as “Classic KS”. It is a relatively indolent disease, often confined to the extremities. It is generally a chronic condition persisting for several years before unrelated fatality. Classic KS is predominant in elderly patients, more frequently men, of Mediterranean, Eastern European, or Middle Eastern origin.<sup>38</sup>

A second form of KS, known as “Endemic KS”, was prevalent in Africa predating the emergence of HIV.<sup>39</sup> It is a much more aggressive form of the disease, often spreading to the lymph nodes and affecting both adults and children.<sup>40</sup> Retrospective examination of medical records from the 1960s indicated that endemic KS accounted for between 4.5% and 7.0% of tumors seen in Ugandan men.<sup>41,42</sup> However, until the 1980s, KS (endemic or classic) remained a relatively rare neoplasm, particularly in North America and Western Europe, where it was almost unseen.

In 1981 an unusual epidemic of KS cases in young men from New York City and San Francisco was one of the first signs of the outbreak of AIDS.<sup>43</sup> This new form of KS, dubbed AIDS-KS, became an AIDS-defining disease and remains the most frequent malignancy in people living with HIV.<sup>44</sup> Since the advent of highly-active antiretroviral therapy (HAART), KS incidence has declined substantially among those with access to these medicines.<sup>45,46</sup> However, AIDS-KS remains one of the most common cancers across Africa, with KS recently estimated to account for 12.9% of all cancers in African males and 5.1% of all cancers in African females.<sup>47</sup> AIDS-KS is an aggressive disease, often affecting the mouth, lungs, gastrointestinal tract, or genitalia.<sup>44</sup>

The 1980s also saw the rise of a fourth epidemiological variety of KS. ‘Iatrogenic KS’ occurs in allograft transplant recipients, and other patients receiving immunosuppressive therapy. KS is up to 150 times more common in transplant recipients than the general Western population. Interestingly, transplant recipients in the West with origins (first or second generation) in countries where classic or endemic KS is prevalent are at greater risk of developing iatrogenic KS. This suggests an increased risk of developing KS among these populations even after geographical relocation,<sup>48</sup> which is likely to be simply explained by a higher prevalence of KSHV infection. There is, however, evidence that iatrogenic KS can arise from both reactivation of pre-transplant KSHV infection and by primary infection through receipt of a KSHV-infected graft.<sup>49,50</sup>

## PATHOLOGY

KS is a complex tumor with three distinct phases referred to as patch, plaque, and nodular grades. Lesions are usually multi-focal, and can arise in the skin, viscera, or mucosa.<sup>38</sup> The KS tumor cell is considered to be the spindle cell, which is distinguished by its spindle-shaped morphology and dominates final-stage nodular lesions.<sup>51</sup> The exact origin of the spindle cell is unclear although recent immunophenotyping and gene expression microarray evidence points towards a lymphatic endothelial origin. Further studies demonstrated that *in vitro* infection of blood endothelial cells with KSHV leads to lymphatic reprogramming of these cells and so it has been suggested that *in vivo*, blood vessel endothelial cells are converted towards a lymphatic phenotype by latent KSHV infection, giving rise to the spindle cell.<sup>51</sup>

Despite their different clinical manifestations, KS lesions observed in the four epidemiological forms of KS outlined above are histologically indistinguishable at comparative stages. At the earliest stage, the patch stage, KS lesions are macular and

characterized by a proliferation of small, irregular endothelial lined spaces surrounding normal dermal blood vessels with an accompanying infiltration of inflammatory lymphocytes (Fig. 35.1a). At the plaque stage, the lesions become palpable, and the abnormal vasculature spreads through the entire dermis and sometimes into the subcutaneous fat (Fig. 35.1b). Clusters of spindle cells expand around the vascular spaces, and varying numbers of erythrocytes fill the channels. Nodular-stage KS lesions develop areas of pigmentation and are composed of sheets and large fascicles of uniform spindle cells, some of which are undergoing mitosis (Fig. 35.1c). Erythrocytes are trapped within

\*c+

\*d+

\*e+

**Fig. 35.1:** Histological stages of Kaposi sarcoma. (a) Early Kaposi sarcoma patch stage with small vessels with hyaline bodies within cells. (b) Plaque stage Kaposi sarcoma with presence of ill-defined spindle cell proliferation forming small vascular spaces and associated with a mild chronic inflammatory cell infiltrate including plasma cells. (c) Nodular Kaposi sarcoma.

an extensive network of slit-like vascular channels. The channels themselves, however, are not well-defined, lacking pericytes in their walls and with fragmentation of their endothelial lining and basal lamina.

An unusual feature of KS tumor biology is the important role played by inflammatory infiltrates, particularly at KS onset. The development of KS may thus be seen as a multi-factorial process in which infection by KSHV is a requirement; immunosuppression is an important cofactor; and, paradoxically, some level of systemic and localized immune activation in the form of increased Th1 cytokine production (induced either by KSHV infection, HIV infection or unknown causes) is also involved. The Th1 cytokine upregulation initiates an inflammatory-angiogenic process that leads to sites of activated tissue that are vulnerable to KS lesion formation.<sup>52</sup> Recruitment of KSHV-infected cells and other PBMCs to these sites establishes a tissue microenvironment that has high levels of inflammatory cytokines and is increasingly rich in KSHV-infected cells of both macrophagic and endothelial origin. This positively reinforces cell recruitment, and promotes the formation and survival of spindle cells and the production of further cytokines, angiogenic factors and growth factors that contribute to the development of advanced KS lesions.

## CLINICAL MANIFESTATIONS

Most patients with KS present with skin lesions that are typically multiple, pigmented, raised, painless and do not blanch (Fig. 35.2). The earliest cutaneous lesions are often asymptomatic innocuous-looking macular-pigmented lesions, which vary in color from faint pink to vivid purple. Larger plaques occur usually on the trunk as oblong lesions following the line of skin creases. Lesions may develop to form large plaques and nodules that can be associated with painful edema (Fig. 35.3). In addition to a thorough skin examination, inspection of the oral cavity (Fig. 35.4) and conjunctivae (Fig. 35.5) should be undertaken. Oral lesions are a frequent accompaniment that may lead to ulceration, dysphagia, and secondary infection (Fig. 35.4). A nodular form of KS that is frequently associated with lymphedema is seen more commonly in people of African descent and often proves particularly difficult to control.

**Fig. 35.2:** Cutaneous Kaposi sarcoma.

Fig. 35.5: Ocular Kaposi sarcoma.

**Table 35.2:** The Modified AIDS Clinical Trials Group Staging of KS<sup>5</sup>

	Good risk (all of the following) T0/I0	Poor risk (any of the following) T1/I1
Tumor (T)	Confined to skin, lymph nodes or minimal oral disease	Tumor-associated edema or ulceration Extensive oral KS Gastrointestinal KS KS in other non-nodal viscera
Immune status (I)	CD4 count >150/ $\mu$ L	CD4 <150/ $\mu$ L

The most common sites of visceral KS are the lungs and stomach. Pulmonary KS is a life-threatening complication that usually presents with dyspnea, dry cough and sometimes hemoptysis, with or without fever. Chest X-ray typically reveals a diffuse reticulonodular infiltrate and pleural effusion. Gastrointestinal lesions are usually asymptomatic but may bleed or cause obstruction. The diagnosis is usually confirmed at endoscopy. The prognosis of patients with AIDS-KS depends upon both the stage of the KS, the level of immunosuppression, and the response to anti-HIV therapy. KS is staged using the AIDS clinical trials group modified staging classification (see Table 35.2).<sup>53</sup>

## TREATMENT

For AIDS-KS patients with symptomatic disease or life threatening visceral disease prompt effective therapy is usually merited, while for patients with asymptomatic indolent lesions HAART alone may result in complete regression. Criteria for evaluating response to therapy have been established (see Table 35.3).<sup>54</sup>

## Highly Active Antiretroviral Therapy

There has been a fall in the incidence of KS both as a first AIDS diagnosis and a subsequent manifestation in HIV seropositive cohorts from established market economies. This decline in KS coincides with the introduction of highly active antiretroviral therapies (HAART) and the relative risk of developing KS is significantly lower among people receiving HAART regimens.<sup>55–59</sup> Indeed the majority of patients with newly diagnosed KS are HAART naïve or have virological evidence of failure with detectable HIV viral loads. A number of case reports and small studies documenting responses of KS to HAART have been published. A study of 78 patients with established KS has demonstrated that the introduction of HAART therapy is associated with a prolongation of the time to treatment failure of KS.<sup>60</sup> Thus HAART therapy has a major influence both on the epidemiology and clinical progression of KS without apparently having a direct effect upon the causative herpesvirus, HHV-8. The postulated mechanism of this effect is the immune reconstitution of cytotoxic T-lymphocyte responses to HHV-8. The response rate to HAART alone is around 60–70% but lesions may take 6–12 months to fade.

**Table 35.3:** Response Criteria for HIV-Associated Kaposi Sarcoma

<b>Complete response (CR)</b>
The complete resolution of all KS with no new lesions, lasting for at least 4 weeks. A biopsy is required to confirm the absence of residual KS in flat lesions containing pigmentation. Endoscopies must be repeated to confirm the complete resolution of previously detected visceral disease.
<b>Clinical complete response (CCR)</b>
Patients who have no detectable residual KS lesions for at least 4 weeks but whose response was not confirmed by biopsy and/or repeat endoscopy.
<b>Partial response (PR)</b>
One or more of the following in the absence of (i) new cutaneous lesions, (ii) new visceral/oral lesions, (iii) increasing KS-associated edema, (iv) a 25% or more increase in the product of the bidimensional diameters of any index lesion: 1. A 50% or greater decrease in the number of measurable lesions on the skin and/or in the mouth or viscera. 2. A 50% or greater decrease in the size of the lesions as defined by one of the following three criteria (a) a 50% or more decrease in the sums of the products of the largest bidimensional diameters of the index lesions; (b) a complete flattening of at least 50% of the lesions; (c) where 75% or more of the nodular lesions become indurated plaques.
<b>Stable disease (SD)</b>
Any response that does not meet the above criteria.
<b>Progressive disease (PD)</b>
Any of the following: 1. A 25% or more increase in the product of the bidimensional diameters of any index lesion. 2. The appearance of new lesions. 3. Where 25% or more of previously flat lesions become raised. 4. The appearance of new or increased KS-associated edema.

## Intralesional Chemotherapy

Localized therapies are advocated for patients with limited cutaneous disease. Intralesional injection of a dilute solution of vinblastine (0.2 mg/mL) using volumes of up to 0.5 ml per lesion is an effective, easy, and well-tolerated treatment for lesions under 1 cm in diameter. Intralesional vinblastine has no significant systemic effects and injections may be repeated 2 or 3 times. This approach is also valuable for small intraoral and gingival lesions.

## Radiotherapy

Larger cutaneous lesions may be treated with radiotherapy and local control is generally achieved. For cutaneous lesions either a single fraction of 8Gy or 16Gy in four fractions is routinely used. Although the response rate and duration of local control may be better with fractionated regimens compared with single fraction treatment, toxicity and patient convenience are worse. Cosmetic improvement is usually achieved although there may be a halo appearance on account of the depigmented margin around treated lesions. Severe mucositis and acute edema reactions may

follow radiation treatment of the oral cavity and feet and for this reason treatment is given in four fractions at weekly intervals. Recurrence of the tumor is common and therefore radiotherapy treatment is usually reserved for symptomatic and cosmetically disturbing lesions.

## Chemotherapy for KS

Chemotherapy is advocated for advanced cutaneous and visceral KS but is not merited for early disease in view of the potential response to HAART. Early single agent studies confirmed the activity of a number of cytotoxic agents. In particular, anthracyclines, vinca alkaloids, bleomycin, and etoposide were found to have clinical activity with observed response rates of 20–60%. In Europe, bleomycin and vincristine (BV) was the most frequently prescribed chemotherapy for KS until the mid-1990s. It is considered safe and effective, the main toxicity being peripheral neuropathy although reduced lung transfer factor is seen with high cumulative bleomycin doses. The addition of adriamycin (ABV) was widely practiced in America and may increase the response rate marginally but results in myelosuppression and alopecia.

## Liposomal Anthracyclines

Liposome encapsulation of anthracyclines constituted a considerable advance in the chemotherapy of KS. The advantages of liposomal formulation include increased tumor uptake and hence favorable pharmacokinetics. Moreover, the liposomal forms are less cardiotoxic than the parent anthracyclines. Both liposome encapsulated daunorubicin (Daunoxome 40 mg/m<sup>2</sup> every 2 weeks) and the pegylated liposomal doxorubicin (Caelyx 20 mg/m<sup>2</sup> every 3 weeks) have been shown to have good antitumor activity. The toxicity profile is better than for other anthracyclines, with no reported cardiotoxicity even with high cumulative dosages and rarely significant alopecia, however there remains considerable myelosuppression, and occasional emesis. In addition, infusion related hypotension and hand/foot syndrome are novel side effects seen with these liposomal formulations. In randomized comparisons of liposomal doxorubicin compared to both ABV and BV as first line therapy for KS, response rates were higher in the Caelyx arms.<sup>61,62</sup> Liposomal anthracyclines are considered first line chemotherapy for advanced KS.

## Paclitaxel

Paclitaxel has been shown to have single agent activity against KS and has a valuable role in the management of refractory disease. The toxicities of paclitaxel are well-recognized although appear to be no worse in patients with HIV than in other groups treated with equivalent dosages. Two studies of refractory KS have shown response rates of 53% and 71% and median response durations of 7.4 and 10.4-month.<sup>63,64</sup> These results have led to the rapid acceptance of paclitaxel (100 mg/m<sup>2</sup> over 3 hours every 2 weeks) as the treatment of choice for anthracycline refractory KS.

## Multicentric Castleman Disease

### PATHOGENESIS

Multicentric Castleman disease (MCD) is a rare, atypical lymphoproliferative disorder of the plasma cell type. It is characterized clinically by generalized lymphadenopathy and evidence of multiorgan involvement.<sup>65</sup> Its close association with KS, particularly in AIDS patients, prompted Soulier et al. to search for the presence of KSHV sequences in MCD samples.<sup>66</sup> They, and others,<sup>67</sup> found that KSHV DNA is detected in MCD lesions from all HIV-related and about 40% of HIV-unrelated cases of MCD. It is therefore likely that there is more than one cause for this unusual disease. Nonetheless, a correlation between increased KSHV viral load in peripheral blood mononuclear cells and clinical MCD exacerbations supports a role for KSHV in MCD pathogenesis.<sup>68</sup> Recently, KSHV-positive MCD has been recognized as a distinct subset of MCD and designated plasmablastic MCD, since it features the presence of large plasmablastic cells all of which harbor KSHV.<sup>69</sup> Unlike KS and PEL, the tumor cells from MCD, express both latent and lytic KSHV proteins.<sup>21,22</sup>

### DIAGNOSIS

The diagnosis of MCD is established histologically by lymph node biopsy or if necessary after splenectomy. The characteristic features are interfollicular plasmablasts that express the KSHV latent nuclear antigen (LANA). These plasmablasts also express high levels of  $\lambda$  light-chain restricted IgM, but are polyclonal and do not contain somatic mutations in their IgG genes, suggesting that they arise from naïve B-lymphocytes.<sup>70</sup> Occasionally, these plasmablasts join together to form clusters or “microlymphomas” and may progress to monoclonal plasmablastic lymphomas.<sup>69</sup>

### CLINICAL MANIFESTATIONS

On examination, patients have diffuse lymphadenopathy, hepatosplenomegaly, and may have ascites, edema, and effusions both pulmonary and pericardial. The clinical manifestations include an acute interstitial pneumonitis<sup>71,72</sup> and hemophagocytic syndrome<sup>73</sup> and less frequently neuropathic problems including polyneuropathies, leptomeningeal, and CNS infiltration as well as myasthenia gravis.<sup>74</sup> Laboratory investigations may reveal thrombocytopenia, anemia, hypoalbuminemia, and hypergammaglobulinemia. The systemic manifestations are thought to be due to interleukin-6 secretion either directly by the tumor or in response to the disease. MCD is a relapsing and remitting disease and the definition of an “attack” has been proposed as a combination of fever and a raised serum C-reactive protein in the absence of other etiology plus three of the following symptoms: peripheral lymphadenopathy, splenomegaly, edema, pleural effusion, ascites, cough, nasal obstruction, xerostomia, rash, central neurological symptoms, jaundice or autoimmune hemolytic anemia.<sup>75</sup>

### TREATMENT

The optimum treatment for Castleman disease remains uncertain. The prognosis is poor with a median survival of 14 months in one published series.<sup>76</sup> However, earlier recognition of the diagnosis and treatment with single agent chemotherapy, monoclonal antibodies to CD20, and splenectomy has recently been shown to result in high remission rates and prolonged survival.<sup>75,77,78</sup> The natural history of Castleman disease follows a relapsing and remitting course and there is a high risk of systemic NHL.<sup>79</sup> High plasma cell-free levels of HHV8 DNA viral load appear to reflect disease activity in Castleman disease and may be useful in diagnosing and monitoring the disease.

## Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is a high grade non-Hodgkin B-cell lymphoma that usually occurs in the context of HIV-infection. PEL presents with lymphomatous effusions in body cavities such as the pleural, pericardial, and peritoneal spaces in the absence of a solid tumor mass. PEL express an indeterminate immunophenotype with clonal immunoglobulin gene rearrangements. PEL was first defined as a unique disease (originally under the name body cavity-based lymphoma) when Cesarman et al. demonstrated the presence of high levels of KSHV DNA in all cases of this atypical lymphoma, but not in any other HIV- or non-HIV-related non-Hodgkin lymphoma.<sup>80</sup> By definition, therefore, PEL patients must show evidence of KSHV infection although the mechanisms by which KSHV promotes oncogenesis in PEL are not fully understood. In addition many PEL are coinfecting with EBV. The clinical management of PEL does not differ from the HIV associated NHL. Patients present with a median CD4 count of  $90/\mu\text{L}^3$  while the median survival in one study is just 5 months.

### Summary

KSHV, which is also known as HHV8 is a gammaherpesvirus identified in 1994 that is implicated in the pathogenesis of not only all forms of Kaposi sarcoma but also some cases of primary effusion lymphomas and multicentric Castleman disease.

## Introduction

Syphilis is a chronic sexually transmitted disease caused by infection with a spirochaete bacterium *Treponema pallidum subsp. pallidum*. It is systemic from the outset, capable of involving every structure of the body in its course, and distinguished by florid manifestations on one hand and years of completely asymptomatic latency on the other. It can simulate many diseases and present to a wide range of medical specialities.<sup>1</sup>

The disease is broadly divided into infectious or early syphilis and non-infectious or late syphilis. Infectious syphilis is a disease of considerable public health importance. This importance particularly relates to adverse pregnancy outcomes (stillbirth and congenital syphilis) and the facilitation of HIV transmission by the ulcerative and inflammatory lesions of primary and secondary syphilis.<sup>2</sup> Syphilis is most infectious through sexual contact or from mother to foetus during the primary and secondary stages; however, transmission may also occur during the period of early latency.

## Epidemiology

Syphilis remains a common infection worldwide and the World Health Organization (WHO) estimated that in 1999 12 million individuals developed early syphilis<sup>3</sup> and it was estimated that in 2006 between 750,000 and 1.5 million pregnancies were affected by syphilis.<sup>4</sup> Most infections are in sub-Saharan Africa and south Asia (in community prevalence studies of women in India the prevalence of infection varies from 0.2% to 10.5%).<sup>5</sup> There is some evidence that the community prevalence of syphilis is falling in some populations in India with the RPR reactivity in voluntary donors decreasing from 0.4% in 2004 to 0.09% in 2006–07.<sup>6</sup> In a sexually transmitted infection (STI) clinic in Gambia, West Africa, the prevalence of serological syphilis dropped from 11.2% in 1994 to 1.5% in 2007.<sup>7</sup> In the US and Europe, transmission of syphilis became rare in the 1970s and early 1980s but has since re-emerged as an important infection.<sup>8</sup> In the US in the 1980s there was a sustained epidemic of early syphilis associated with crack cocaine use and disproportionately affecting African-Americans.<sup>9</sup> After the break-up of the Soviet Union, the social

Fig. 36.1: Natural history of syphilis (Modified and redrawn from Reference 211).

disruption and collapse of public health services resulted in a huge epidemic of syphilis that affected the syphilis rates in neighboring countries.<sup>10</sup> In Western Europe since the late 1990s, there has been a re-emergence of syphilis, particularly affecting gay men many of whom have previously been diagnosed with HIV.<sup>11</sup> The numbers of men and women diagnosed in STI clinics in the UK since 1931 are shown in Fig. 36.1. This graph shows the epidemic of syphilis during the Second World War and its re-emergence among gay men in the 1970s and 1980s. This is followed by its virtual eradication as an endemically transmitted infection in the mid 1980s and re-emergence in gay men in the late 1990s.

## Incubation Period

After sexual contact with someone who has early syphilis, approximately one-third of individuals will develop a primary chancre. The incubation period (IP) for primary chancre has been found to vary in natural and experimental infections, and probably depends on inoculum size. The mean primary IP (period between infection and appearance of primary chancre) in experimental infection has been found to be 25 days and in

the natural infection 31 days. Although the commonly quoted range of IP is 9–90 days, the variation is usually much less. The available data indicate that in most cases, the primary IP varies between 3 and 4 weeks.<sup>12</sup>

### Primary Chancre, Secondary IP, and Secondary Eruption

After the primary IP a primary chancre appears at the site of inoculation. Most primary chancres heal before secondary lesions emerge. Virtually all people with syphilis develop secondary syphilis, but the manifestations may be so mild that they may go unnoticed or do not prompt individuals to seek treatment.<sup>13</sup> The average duration for a chancre to heal is 12 days. However, in 12–34% women and 56–63% men, the chancre may persist and be present during the appearance of the secondary rash.

The average secondary IP (period between contact and appearance of secondary rash) is approximately 8 weeks. In some people, the eruption may develop later, but almost always within 6 months. The data from the Oslo study suggest that the symptoms of secondary disease last for an average of 3.6 months with a range of 1–12 months.<sup>14</sup>

Approximately 25% of individuals develop a relapse of secondary disease. Further, 5% of patients may have 2 relapses and 1%, 3 relapses. Two-thirds of these relapses occur within 6 months, 90% within one year, 95% within 2 years, and 100% within 5 years.<sup>15</sup>

### Latent Stage

After the secondary stage resolves, the individual then remains in an asymptomatic stage, termed “latency.” During this stage, the only evidence of infection is positive syphilis serology. An arbitrary distinction between early and late latent syphilis is used primarily to guide decisions regarding treatment. As most relapses of the secondary syphilis rash occur in the first year of infection, this period is defined as early latent (infectious) syphilis and the later period as late latent (non-infectious) syphilis by the European (European Centre for Disease Prevention and Control)<sup>16</sup> and Centers for Disease Control and Prevention (CDC) (US) guidelines.<sup>17,18</sup> WHO<sup>19</sup> and the UK<sup>20</sup> use a two-year period to define these terms.

### Late Syphilis

Approximately, two-thirds of patients with late latent syphilis are considered to have spontaneous cure with no clinical or pathological evidence of infection.

About 15–40% patients develop recognizable late complications of syphilis. The results of Oslo study showed that over a period of 35 years, late benign (gummatous) syphilis had developed in 15.8% of patients. Cardiovascular complications developed in 10.4% (14% of male and 8% of female) patients and neurosyphilis in 6.6% (9% of male and 5% of female) of patients. In the Oslo study, syphilis was considered as a cause of death in about 10% of patients. Late syphilis is rarely encountered in immunocompetent

persons these days which is probably partly due to better syphilis control and effective treatment and partly because of the benefit of the inadvertent use of antibiotics for other diseases.<sup>13</sup>

### Biology of *Treponema Pallidum*

Until recently the taxonomy of spirochetes was not well-developed because of difficulties experienced in growing many important species of spirochaetes *in vitro*. The information about their biochemical and other phenotypic properties was lacking, and classifications, often inappropriate, were largely based on morphological, ecological, and epidemiological criteria. *T. pallidum* (Fig. 36.2) is the causative agent of syphilis, however, because of close genetic homology, *T. pallidum* of venereal syphilis (*subsp. pallidum*), yaws (*subsp. pertenue*), and endemic syphilis (*subsp. endemicum*); all have been assigned to the same species.<sup>21,22</sup> Recently, however, a genetic signature was defined in the 15-kDa lipoprotein gene (*ttp15*) of *T. pallidum subsp. pallidum* that distinguishes it from *T. pallidum subsp. pertenue* and *T. pallidum subsp. Endemicum*.<sup>23</sup> *T. carateum*, the causative agent for pinta, is still considered a separate species due to the lack of genetic information.<sup>24</sup>

Nichols first isolated *T. pallidum* in 1912 from the spinal fluid of a patient with syphilis with neurological involvement. Since then, this strain has been maintained in the laboratory in rabbit testicles for experimental purposes and known after him as Nichols strain.<sup>25</sup> Subsequently, in 1982, Penn et al.<sup>26</sup> isolated another strain from human chancres and cultivated it in rabbit testicles. This strain was less virulent than Nichols strain.

*T. pallidum* is a thin, delicate, pale, motile, regularly close-coiled spiral spirochete with tapering ends. Because of its thinness, it cannot be visualized by conventional light microscopy, and dark ground illumination (DGI) is required to observe it. Under DGI, it can be recognized by its characteristic movements, which include slow forward and backward movement, rotating on its long axis like a corkscrew, and a compression, expansion and bending (flexuous) movement.<sup>27</sup> *T. pallidum* varies from 8 to 16  $\mu\text{m}$  in length and 0.1–15  $\mu\text{m}$  in width.<sup>28</sup> The wavelength of the

**Fig. 36.2:** Negative stain electron micrograph of *Treponema pallidum*. Courtesy: Arya OP, Hart CA, eds. *Sexually Transmitted Infections and AIDS in the Tropics*. Wallingford: CAB International, 1998; Fig. 7.1.2.

organism is about 0.9  $\mu\text{m}$  with amplitude of 0.2  $\mu\text{m}$ . It has 8–20 regularly placed, rigid coils with a distance of 1  $\mu\text{m}$  between each coil. The terminal part of *T. pallidum* is formed by an acron-like nose piece of about 50 nm  $\times$  60 nm. These nose pieces are thought to be responsible for attachment of the organism. The central cytoplasmic body is enveloped in a 7 nm thick triple layered cytoplasmic membrane or outer membrane. This contains 100-fold less membrane spanning proteins compared with outer membranes of other typical gram-negative bacteria.<sup>29,30</sup> The low-protein content of exposed outer membrane helps the organism evade the host immune response during chronic infection.<sup>31</sup>

Three or four endoflagella are inserted in a row on the tapering terminal portion at each end of the organism. They originate from the subterminal regions of cytoplasmic body. Endoflagella from both ends of the cell extend up to more than half of the length of the organism and interdigitate over its central portion.<sup>32–33</sup> These endoflagella are probably responsible for the characteristic motility of treponemes.

The genome sequence of *Treponema pallidum subsp. pallidum* has recently been elucidated.<sup>34</sup> The sequence and predicted function of over 1000 genes will greatly facilitate research in the genetic characteristics, physiology, antigenic structure and pathogenesis of this bacterium. The organism has been shown to have extremely limited metabolic capabilities for instance it is unable to synthesize ATP, lacks proteins for iron transfer and is unable to manufacturing some nucleotides and most amino acids. On the other hand many of the genes whose function has been elucidated code for transport proteins confirming that *T. pallidum* is highly dependent on its host and explaining the fastidious nature of this organism *in vitro*.<sup>35</sup> These advances are expected to promote the refinement of conditions for *in vitro* culture, an improvement of diagnostic tests, the development of vaccines and an improved understanding of pathogenesis and manifestations of syphilis.<sup>33</sup>

## CULTURE

*T. pallidum* is considered a non-cultivable bacterium *in vitro*. However, the organism has been successfully grown in mammalian tissue culture cells.<sup>34</sup> However poor yields are obtained and serial subcultures *in vitro* are difficult to achieve. Therefore, the only practical method for the culture of *T. pallidum* at present is inoculation in rabbit testes. Treponemal suspension is injected into the body of the testis. After a week, the testis becomes firm and then, in the next few days, enlarges rapidly due to a diffuse orchitis.<sup>36</sup>

Although, the organism was considered a strict anaerobe in earlier reports, it has now been realized that an oxygen concentration of about 3% in the gaseous phase is helpful for optimum growth.<sup>37,38</sup> The balance of oxygen utilization and toxicity is the key to the survival and growth of *T. pallidum*.

The metabolic capabilities and adaptability of *T. pallidum* are minimal. This relative deficiency can be explained by the absence of many metabolic pathways, including tricarboxylic acid cycle, components of oxidative phosphorylation and most biosynthetic pathways. The genome sequencing of *T. pallidum* has confirmed

the inability of the organism to synthesize enzyme cofactors, fatty acids, and nucleotides *de novo*.<sup>35,39,40</sup>

*T. pallidum* is an extremely delicate organism that is sensitive to low concentrations of detergents, desiccation and raised temperature. Exposure of *T. pallidum* to 41.5°C for 1 hour is lethal and before the discovery of penicillin, induced fever, either by malaria therapy or artificially by “Kettering hyper-therm,” was a popular and partially effective treatment modality for syphilis.<sup>41</sup>

## Immunology of Syphilis

Animal experiments during the earlier half of the 20th century have shown that shortly after the development of a primary lesion, a second primary lesion cannot be easily produced on re-inoculation. This phenomenon is known as chancre immunity.<sup>42</sup> Re-inoculation of a rabbit on the site of a previous chancre met with decreasing success as the age of first infection increases. However, human inoculation experiments carried out during the same period showed that a chancre can be produced in man while the first chancre is progressing, while inoculation of organisms during the secondary stage produces papules and during tertiary stage, gummata. Immunity to chancre formation is well-marked in early latency, and this lessens with the passage of time.<sup>42</sup>

*Treponema pallidum subsp. pallidum* establishes a lifelong chronic infection in the absence of appropriate treatment. The immune response evasion mechanisms employed by *T. pallidum* are poorly understood.<sup>43</sup> One of the factors contributing to immune evasion is poorly exposed immunogenic surface proteins in the outer membrane (*T. pallidum* rare outer membrane proteins-TROMPs).<sup>44</sup> These highly immunogenic proteins of *T. pallidum* are lipoproteins anchored predominantly to the periplasmic leaflet of the cytoplasmic membrane, protected by the less immunogenic outer membrane.<sup>45</sup> In addition, *T. pallidum* may have a complex system of antigenic variation for immune evasion.<sup>46</sup>

The cell-mediated inflammatory processes triggered by treponemes within infected tissues have two distinct, yet interrelated, consequences. On one hand, they cause the tissue damage which is responsible for clinical manifestations, while on the other hand, they are responsible for the clearing of treponemes, a prerequisite for the resolution of lesions.<sup>47,48</sup> Cellular infiltrates in syphilitic lesions are mainly composed of lymphocytes, macrophages and plasma cells. Immunohistochemical analyses have shown that these infiltrating cells are activated T cells and that these T cells release cytokines consistent with a Th1 type of response.<sup>49,50</sup> Dendritic cells have a key role in presenting *T. pallidum* to T lymphocytes in the regional lymph nodes causing T lymphocytes to proliferate and migrate to the site of infection. In the lesions of primary syphilis helper (CD4+) T cells predominate and in secondary syphilis lesions cytolytic (CD8+) cells predominate. These T cells activate macrophages and stimulate B cells to produce antibodies against *T. pallidum* and it is likely that the resulting inflammatory response causes the clinical manifestations of syphilis and tissue damage.<sup>51</sup> In one study, a delayed tuberculin type skin responses were induced in

patients with late acquired or congenital syphilis by the repeated inoculation of material obtained from rabbit syphilitic testes. However, this test is usually negative in patients with early syphilis.<sup>42</sup>

This partial “anergy” in the early infectious stage disappears with treatment or with the progression to non-infectious late stage disease. It is specific to syphilitic antigens, and reaction to other intradermal tests remain normal in these patients. This partial inhibition of the cell mediated immune response is thought to be responsible for the persistence of infectiousness for prolonged periods and for the ease of demonstrating treponemes in tissues. In late stages, treatment has no effect on the positive intradermal test with syphilitic antigens. The initial inhibition of the immune response in early syphilis is reflected by the finding of depletion of lymphocytes in the para-cortical (thymus dependant) areas of lymph node; however, the mechanism of this active suppression of cell mediated immunity is not understood. A plasma factor depresses phytohemagglutinin lymphocyte stimulation in infectious syphilis. Antigen-antibody immune complexes formed during early stages of syphilis have also been thought to suppress delayed hypersensitivity reactions. The role of genetic factors is not clear.<sup>52</sup>

Several experimental studies have provided evidence in support of a major role of humoral immunity in defence against *T. pallidum*.<sup>53,54</sup> These include immune serum passive protection.<sup>55,56</sup> inhibition of *T. pallidum* adherence and invasion of cultured cell monolayers by immune serum, immune serum mediated phagocytosis of *T. pallidum* by rabbit peritoneal macrophages,<sup>57</sup> and immune serum complement-dependent treponemicidal antibody.<sup>58</sup> Further, it has been demonstrated that a close quantitative correlation exists between the development of acquired resistance and the level of treponemicidal antibody, suggesting that killing antibody plays a major role in the acquisition of protective immunity.<sup>59</sup>

## Pathogenesis

*T. pallidum* is presumed to penetrate through small breaks in the skin or mucosa.<sup>60</sup> Intact skin, and to a lesser extent, intact mucous membranes, do provide a barrier to syphilitic infection in man. However, animal experiments have shown that male rabbits may be infected by exposing the normal mucous membrane of the prepuce to a treponemal suspension suggesting that protection provided by intact mucous membrane is not absolute.<sup>61</sup> Magnuson et al.<sup>62</sup> in their study on four human volunteers, successfully produced dark field positive lesions by injecting virulent *T. pallidum* in doses of 10, 100, 1000 and 10,000 organisms on the forearm.

The 50% infectious dose was calculated to be 57 organisms.<sup>61</sup> Animal studies have shown that the organisms appear within minutes in lymph nodes and disseminate widely via the bloodstream within hours.<sup>63,64</sup> How it enters the cell is not exactly known. It has been shown to adhere rapidly to mammalian cells in tissue culture.<sup>65</sup> It requires an epithelial

surface to attach and penetrate the tissue.<sup>66</sup> Attachment may occur by specific attachment ligands.<sup>67–69</sup> *T. pallidum* increases interstitial collagenase levels when added to human dermal fibroblast culture. This suggests that *T. pallidum* can stimulate host human fibroblasts to increase the synthesis of interstitial collagenase which may act as a virulence factor and probably help the organism to penetrate the cell.<sup>70</sup>

After penetration, the organisms multiply slowly at the site of inoculation without producing a clinically overt lesion. When the number reaches a threshold level, unknown mechanisms induce formation of the primary lesion, which is a raised, firm, erythematous, and painless ulcer (which may be preceded by a papule which then ulcerates). The primary lesion is full of organisms which are usually easily detected by dark ground examination. A combined humoral and cell-mediated immune response appears to eliminate the pathogen locally resulting in complete healing. Spirochaetemia occurs early during the evolution of the primary chancre, therefore healing of primary lesion does not prevent development of the secondary stage. Most patients progress to the secondary stage, characterized by lesions scattered on the skin and (usually asymptotically) many other organs. Like the primary lesion, organisms are found in large numbers in the secondary lesions.<sup>22</sup> At this stage, circulating immune complexes have been identified, which may contain a small number of treponemal antigens.<sup>71</sup> In the secondary stage there are a number of autoimmune responses that have been reported<sup>22</sup> including to cardiolipin, fibronectin, collagen, laminin, and creatine kinase. The antibody response against treponemes is responsible for the relatively mild nature of generalized disease, which might otherwise resemble generalized, multiple primary chancres.

The secondary stage also involutes spontaneously and is followed by a period of long latency, which may last many years or result in spontaneous cure of infection. It is assumed that during latency treponemes are sequestered in small numbers at immunologically protected sites in the body. Eventually the tertiary stage may develop, which may manifest either in its serious form as cardiovascular syphilis or neurosyphilis, or as more benign gummatous lesions in skin and other organs.

During this stage, treponemes are characteristically sparse with the exception of general paresis, in which there is often an abundance of treponemes in cerebral tissue.<sup>52</sup> Some immunological mechanisms rather than direct damage by treponemes are thought to play important role in the pathogenesis of late syphilis. The local cellular response in the affected tissues in tertiary syphilis resembles a delayed type of hypersensitivity reaction to a very small number of organisms.

## Transmission of Disease

Syphilis spreads through contact with infectious lesions or body fluids. It is acquired through direct sexual contact with an infected person in the early stages of disease or from mother to foetus. Late stages of syphilis are non-infectious.

Studies from the pre-antibiotic era found that nearly 30% of sex partners of persons with primary and secondary syphilis develop the disease.<sup>72</sup> Later studies have shown that almost half of the homosexual or heterosexual contacts of patients with primary and secondary syphilis were infected.<sup>73</sup> Epidemiologic analysis from sub-Saharan Africa showed a transmission possibility in early infectious syphilis of approximately 0.3 from male to female and 0.2 from female to male. The variable factors that influence transmission of infection include the number of exposures, the type of sexual activity, and the morphology and distribution of lesions in the infected partner or partners.<sup>74</sup>

Rarely, non-sexual, non-materno-fetal transmission of the disease can occur in healthcare workers, and in infants and children. The term “syphilis brephotrophica” was coined by Jadassohn referring to syphilis transmitted while performing baby care or handling children.<sup>75</sup> The term lues insontium has also been used to describe non-sexual transmission in general.<sup>76</sup> Studies in the pre-antibiotic era suggested a rate of about 23% of non-sexual transmission of syphilis in children.<sup>76,77</sup> However at that time, the magnitude of sexual abuse was largely unrecognized. Current studies have shown that in the US, as many as 1 in 4 girls and 1 in 7 boys are victims of child sexual abuse and majority of these victims do not show any physical signs. Therefore, the incidence of non-sexually acquired syphilis in children is likely to be much less than that reported in the pre-antibiotic era.<sup>78</sup> Breastfeeding does not result in the transmission of syphilis, unless an infectious lesion is present on the breast. In patients with syphilitic lesions on the lips or oral cavity, kisses may also be a mode of transmission.<sup>79</sup>

A rare route of transmission of syphilis is parenteral transmission via injection drug use or by blood components. Routinely, donated blood is screened for syphilis by serological tests. However, these tests may be negative in some patients with early primary syphilis, who may have a spirochaetemia. However, treponemes remain alive in blood stored at 4°C for only for 2–3 days, minimizing the risk of transmission.<sup>80</sup> In addition to this many patients who receive blood products also receive antimicrobials for their disease, which are treponemocidal. Thus the chances of transfusion transmitted syphilis are minimal. Patients receiving fresh blood are at relatively higher risk of transmission if the donor is in the window period for the serological diagnosis of primary syphilis. Transfusion transmitted syphilis presents directly as secondary syphilis (bypasses primary stage) and is known as “syphilis d’emblée.”<sup>81</sup> Recently, transmission of syphilis during hemodialysis has been reported in patients with end-stage renal disease.<sup>82</sup> Most of the patients who acquired syphilis by hemodialysis were found to have latent disease.<sup>83</sup>

## Clinical Features

### PRIMARY SYPHILIS

After an IP of 9–90 days, the primary chancre appears at the site of inoculation. A small dull red macule appears initially, which soon becomes a papule and subsequently ulcerates to form a

**Fig. 36.3:** Classic hunterian chancre—a single, painless, indurated ulcer with clearly defined borders.

chancre, which is the classical lesion of primary syphilis. The classic hunterian chancre is a single, painless, indurated ulcer, round to oval in shape, clearly defined, with rolled borders and a “ham colored” smooth base but sometimes may be covered with a grayish slough or slightly hemorrhagic crust (Fig. 36.3). The size of the chancre varies from 0.3 cm to 3 cm.

The induration of ulcer on the inner side of prepuce often gives rise to flip on retraction of the preputial skin. This sign is known as the “dory flop.” Kissing ulcers occur on the urethral meatus and coronal sulcus (Figs. 36.4 and 36.5). An ulcer may occur at the hilt of the shaft of the penis, when it is called a “condom chancre.”<sup>84</sup> Though the classical clinical features are quite typical for chancre, these may be absent in almost half of the patients. In one prospective series of patients with primary syphilis one third of HIV negative patients and two thirds of HIV positive patients presented with multiple primary ulcers.<sup>84</sup> So, multiple chancres are not uncommon and in various patient series, have been reported

**Fig. 36.4:** An indurated papule of primary chancre with inguinal lymphadenopathy. The intense inflammation seen in the lymphnode is due to secondary bacterial infection. *Courtesy: Dr. Somesh Gupta.*

**Fig. 36.5:** Primary syphilis—kissing ulcer in coronal sulcus.

to occur in 18–53% of patients with primary syphilis.<sup>85,86</sup> The classic features of primary chancre (painless, indurated, single ulcer with a relatively clean base) have a sensitivity of only 31% but a specificity of 98%.<sup>87</sup> Anderson noted that painful lesions were present in 25% of the patients with primary syphilis and non-indurated lesions were seen in 33%.<sup>88</sup> Mixed infection with *Haemophilus ducreyi* and herpes simplex are common and may produce atypical lesions. Administration of antimicrobials can also change the clinical picture at presentation.

In men, the chancre on the genitalia is seen on the coronal sulcus (35%), glans (29%), shaft (22%), prepuce (19%), frenulum (10%), and in the urinary meatus (1%). In women, genital chancres are seen on the vulva, vagina, or the cervix (Figs. 36.6 and 36.7). The cervix is involved in as many as 44% of patients; however, this is rarely detected unless speculum examination is carried out.<sup>89</sup>

**Fig. 36.6:** Primary chancre on the vulva.

**Fig. 36.7:** Primary chancre in the cervix. Courtesy: Arya OP, Hart CA, eds. *Sexually Transmitted Infections and AIDS in the Tropics*. Wallingford: CAB International, 1998;Plate 32.

Extragenital chancres occur in 12–14% of patients with primary syphilis.<sup>90</sup> These usually result from contact with genital or extragenital lesions in the partner during sexual foreplay, or during anal or oral sex. Rarely, they may occur as a result of inoculation with infected syringes and tattoo needles or a human bite.<sup>91–93</sup> Anorectal chancre is more frequently seen in homosexual men who have receptive anorectal sex. Chancres at these locations are often asymptomatic and may mimic anorectal cancer.<sup>94</sup> In a large series, anorectal chancres were seen in 34% of homosexual men and 7% of women. Oral lesions were seen in 1–3% of women and homosexual men but are likely to be considerably commoner than this and are likely to be either sub-clinical or undiagnosed. A recent study from the UK suggested that up to 35% of syphilis infections among gay men were attributable to oral sex suggesting that oral chancres are likely to be common. Chancres at these locations are exceedingly rare in heterosexual men.<sup>95</sup> Syphilitic chancre may also appear on hands and arms, and rarely, it may present as paronychia.<sup>96</sup>

Chancres are accompanied by regional lymphadenopathy in 50% of cases, which resolves spontaneously in about 4–6 weeks.

*Monorecidive or chancre redux* is the recurrence of a primary sore at the site of the original lesion.<sup>97</sup> It is considered as by some clinicians to be a form of relapse.<sup>1</sup>

*Pseudochancre redux* also occurs at the site of the original chancre; however, unlike true chancre redux, it is noninfectious granulomatous lesion of late syphilis from which treponemes cannot be recovered. The histopathology of this lesion shows granulomatous foci with necrosis and giant cell reaction.

The syphilitic balanitis of Follman is an inflammatory reaction of glans penis in primary syphilis to *T. pallidum*, which may develop instead of, before, after or simultaneously with the primary chancre. Numerous treponemes are present in the lesion which can be demonstrated by DGI or in histologic sections. The balanitis is superficial as the organisms are seen only in epidermal cell layers. The condition is likely to be much more common than is generally supposed, as many cases go unnoticed or unreported.<sup>98</sup>

Syphilis d'emblée is defined as syphilis without chancre. It is a consequence of direct inoculation into the blood as a result of transfusion of infected blood or blood components or puncture with an infected needle. As the inoculation is directly into the blood, generalized syphilis develops without a local reaction.

**Complications** of primary chancre include edema, phimosis, erosive balanitis, lymphangitis, and thrombophlebitis of the dorsal vein. Phagedenic chancre is due to co-infection with fusospirochaetes. It is characterized by necrotizing perforation of prepuce, or in some patients, gangrene.<sup>99</sup>

**Differential diagnosis:** Other STI-related causes of genital ulcers like genital herpes, chancroid, donovanosis, and lymphogranuloma venereum (LGV) should be ruled out. Non-STI related causes like Behçet disease, Crohn disease, squamous cell carcinoma, and fixed drug eruption should also be considered in the differential diagnosis.

## SECONDARY SYPHILIS

The primary chancre resolves on its own after a period of 2–6 weeks (the average time to healing is 21 days). In about 10% of patients a depressed thin scar is left, which may be an important diagnostic clue in patients presenting with the rash of secondary syphilis. There may be no sharp demarcation between primary

**Fig. 36.8:** Subpreputial discharge due to persistent chancre and rash of secondary syphilis on hands.

and secondary syphilis and in 10–40% patients the chancre may persist even after appearance of the secondary rash (Fig. 36.8).

The clinical manifestations of the secondary stage are protean and can involve any organ.<sup>100</sup> Some patients may develop a flu-like prodrome manifesting as fever, malaise, headache, stiff neck, myalgia, arthralgia, and rhinorrhea. However, skin rash and lymphadenopathy are the most common manifestations of secondary syphilis and are seen in 67–92% and 63–100%, of patients respectively (Fig. 36.9). Although the skin rash is the most common presenting feature of secondary syphilis, as many as 60% of patients with serological

**Fig. 36.9:** Frequency of various manifestations of secondary syphilis in different studies. (From Reference 143).

**Fig. 36.10:** Papular rash of secondary syphilis.

evidence of syphilis do not recall any symptoms or signs suggestive of early syphilis. The rash is often subtle, sometimes consisting of one or two lesions that may pass unnoticed.<sup>101</sup> Although the rash is often described as non-pruritic, 8–42% of the patients complain of some degree of itching.

The rash may be macular, papular, maculopapular (Fig. 36.10), papulosquamous, psoriasiform, annular, pustular, or follicular.<sup>102</sup> Macular or maculopapular rash is the commonest form and seen in about 50% of the patients. Classically, the lesions are described as “raw-ham” or copper colored; however, this characteristic color may be absent in patients with pigmented skin. The rash is usually distributed bilaterally and symmetrically. Macular eruptions, also known as roseola syphilitica, consist of 0.5–2 cm pink, discrete, round to oval, macules distributed over trunk, flexor aspects of the upper extremities and palms and the soles. The face is usually spared. Papular and papulosquamous eruptions evolve from macular lesions. Papules along the hairline on forehead are sometimes arranged in a crown-like pattern that is known as “corona veneris.” Some lesions become scaly and may closely resemble psoriasis and lichen planus. Other morphological variants include follicular, lenticular, corymbose, and annular types. Follicular syphilis is more often associated with pruritus. There is deep dermal tenderness that is elicited by applying pressure with a blunt side of a pin over a papule. This sign is considered pathognomonic for syphilis and is known as the Buschke Ollendorf sign. The resolving rash may leave behind depigmented patches on the back and sides of the neck referred to as leukoderma syphiliticum and described as the “necklace of venus.”

The rash of secondary syphilis has certain characteristics that help to distinguish it from other dermatoses. The rash is generalized, involving both skin and mucous membranes, is

**Fig. 36.11:** Secondary syphilis rash on palms.

bilateral and symmetrical, and more prominent on the upper extremities than on the abdomen and lower extremities. It has a special predilection for palms and soles (Fig. 36.11). On the trunk it tends to favor lines of cleavage. The lesions are more often discrete than confluent, are sharply demarcated, and have a coppery hue (Fig. 36.12). However, these characteristic lesions are seen more frequently in Caucasians than in Asians and Africans. In Africans, the lesions tend to be confluent (Fig. 36.13), less well-demarcated, and dull red in color.<sup>103</sup>

Although nodular lesions are characteristically seen in late syphilis they have also been described in secondary syphilis.<sup>104</sup> This variant of secondary syphilis is very rare and less than 20

**Fig. 36.12:** Bilateral, symmetrical rash of secondary syphilis. The lesions are discrete and well-demarcated.

**Fig. 36.13:** Confluent lesions of secondary syphilis.

**Fig. 36.14:** Lichenoid rash of secondary syphilis in a HIV-positive woman.

cases have been described in the literature.<sup>105</sup> Histologically, these lesions may show an atypical lymphoid hyperplasia resembling cutaneous lymphoma (pseudolymphoma).

Lichenoid syphilis is characterized by maculopapular lesions with a lichenoid (violaceous) hue (Fig. 36.14). It had been described frequently in the pre-penicillin era. A recent increase in its incidence may be attributable to the HIV epidemic.<sup>106</sup>

The annular syphilid is seen mostly in black patients. It consists of annular lesions on the face, anogenital area, axillae, palms, and soles. The lenticular syphilid manifests as pinhead to lentil or bean-sized papules on face and genitalia.

Corymbose or bombshell-like eruptions are characterized by a central plaque and surrounding smaller satellite papules. This is very rare and usually appears many months after the initial infection.<sup>107</sup>

In warm and moist areas of the body, such as the genitals, perineum, perianal region, under breasts, axilla, and groin, the skin and mucosal lesions of secondary syphilis may proliferate into pale, elevated, moist sharply demarcated papules with flat surfaces. These lesions are known as condylomata lata, (Figs. 36.15 to 36.17) are highly infectious, and are seen in 25–60% of patients with secondary syphilis. At the labial commissures and nasolabial folds, these lesions become elevated and fissured and are called “split papules” (Fig. 36.18).

Mucous membrane involvement is common in secondary syphilis. Mucous patches are a manifestation of the secondary syphilis rash in the oropharynx and at other mucosal sites

**Fig. 36.15:** Condylomata lata in axilla and rash on palm. *Courtesy: Sanjeev Gupta, Kamal Aggarwal, and VK Jain, Rohtak, India.*

**Fig. 36.16:** Condylomata lata on the under-surface of the penis.

(Figs. 36.19 and 36.20). Oropharyngeal infection clinically ranges from asymptomatic inflammation to severe pharyngitis and occurs in 4–17% of cases. Mucosal lesions are in the form of serpiginous ulcers described as “snail track” ulcers, superficial erosions, papules, and plaques. Lesions resembling oral hairy leukoplakia have been described.<sup>108</sup> The oral mucosa, tongue, lips, palate, pharynx, larynx, tonsils, epiglottis, and aryepiglottic folds may be affected.<sup>109</sup> In addition to oropharynx, they can also occur on the genital mucosa. Mucosal lesions on genitalia are more

**Fig. 36.19:** Mucous patch on tongue.

**Fig. 36.20:** Mucous patches on labial mucosa.

common in women because moisture, friction and some irritation favor their development. They may occur on external genitalia as well as on the cervix. All these moist lesions on the skin or mucosa contain numerous treponemes and are highly infectious.

The follicular rash on the scalp may give rise to two patterns of hair loss. Irregular non-scarring patchy alopecia, which is known as “moth-eaten” alopecia (Fig. 36.21), usually occurs at the margins of the scalp or, rarely, in other hairy areas including

**Fig. 36.21:** “Moth-eaten,” patchy alopecia.

the beard, eyebrows, and legs.<sup>110</sup> Telogen effluvium has also been noted in patients with secondary syphilis.<sup>111</sup>

Rarely, involvement of the nail fold or nail matrix by the rash of secondary syphilis results in nail changes, which include pitting, onycholysis, onychodystrophy, and Beau's lines.

Systemic manifestations of secondary syphilis include malaise, fever, mild hepatitis with elevated<sup>127</sup> liver enzymes, iritis, uveitis,<sup>112</sup> arthritis, parotitis,<sup>113</sup> pulmonary changes, and glomerulonephritis. Neurological involvement is common but is often asymptomatic. A study by Rolfs and co-workers demonstrated that *T. pallidum* invades the central nervous system in at least a quarter of the patients with early syphilis regardless of their HIV status.<sup>114</sup> This can be detected on CSF examination, which may show elevated WBC count and proteins and a reactive CSF VDRL. There is more recent evidence that HIV infection (particularly immunosuppression caused by HIV) is associated with a significantly greater rate of CSF changes.<sup>115</sup> Some case reports suggest an accelerated course of syphilis in patients with immunosuppression caused by concurrent HIV infection. These patients appear to have a greater risk of developing CSF abnormalities and asymptomatic neurosyphilis in the second stage of the disease.<sup>116</sup>

Headache is present in up to one-thirds of patients and fever is usually low grade, seldom exceeding 37.8°C.<sup>117</sup> Gastrointestinal symptoms include anorexia, nausea, and occasionally vomiting. Syphilis of the stomach is rare and manifests as mucosal erosions, rugal hypertrophy, or shallow ulcers involving the antral and pyloric area.<sup>118</sup>

Hepatosplenomegaly is reported to occur in 4–23% of patients and jaundice in up to 12% of patients with early syphilis.<sup>100,119</sup> In a study of liver abnormalities in early syphilis, three of 22 patients showed a well-established non-specific reactive hepatitis on histopathological examination. Serum alkaline phosphatase was abnormal in 45% of patients and minimal total hyperbilirubinemia was present in 32% of patients.<sup>120</sup>

Vague bone pain and arthralgia are common but frank arthritis is rarely reported. A retrospective notes review revealed that of 1800 patients with early syphilis, less than 0.2% had evidence of periostitis.<sup>95</sup> Syphilitic periostitis in early syphilis is probably due to vasculitis.<sup>121</sup> Kidney involvement is extremely rare, but asymptomatic proteinuria is well-documented. Other renal manifestations include nephrotic syndrome, rapidly progressive glomerulonephritis, and renal failure.<sup>122</sup>

Cardiovascular complications in secondary syphilis are rare but myocarditis and ventricular arrhythmia in secondary syphilis are well-documented.<sup>123,124</sup>

Lymphadenopathy involving two or more groups is seen in 60–100% of patients. Enlarged lymph nodes are rubbery, painless, discrete, and non-tender. The occipital, axillary, inguinal, and epitrochlear groups of lymph nodes are most commonly involved.

Lues maligna or malignant secondary syphilis is an explosive, widespread form of secondary syphilis that is characterized by a prodrome of fever, headache, and myalgia, followed by a papulo-pustular eruption that rapidly transforms into necrotic,

sharply margined ulcers with hemorrhagic brown crusts that are organized in rupoid layers.<sup>125</sup> The term lues maligna was coined by Bazin and Dubue in the mid 1800s to describe mutilating noduloulcerative variant of secondary syphilis.<sup>126</sup> It was considered to be a common form of syphilis seen during the great epidemic of the 15th century<sup>127</sup> although Cripps et al.<sup>128</sup> found this might not be the case on reviewing the literature. At that time, the characteristic patient with malignant syphilis was described as an alcoholic in poor health who was malnourished and cachectic. These conditions are postulated to cause depression of immunity. Since the turn of the century, there have been only a few reports of lues maligna with just 18 cases described in the English literature. Sixteen of these were men.<sup>126</sup> With the onset of HIV epidemic, several cases of lues maligna in association with HIV infection induced immunosuppression have been reported.<sup>128</sup> Sands et al.<sup>129</sup> reviewed cases of lues maligna reported in the English literature between 1989 and 1994 and found that 11 of 12 cases had concurrent HIV infection. In a multi-centre retrospective study, 7.3% of the patients with secondary syphilis with concurrent HIV infection were found to have ulcerating secondary syphilis, suggesting that this form is 60 times more common in HIV seropositive than in general population.<sup>130</sup> However, recently malignant syphilis has been described in Russia among people with chronic alcohol misuse.<sup>131</sup> Niesser described four clinical characteristics of malignant syphilis<sup>132</sup>: short IP, prodrome, pleomorphic lesions, and noduloulcerative lesions of the skin and mucosae. Mucosal lesions may be milder and in the form of just mucosal patches; however, occasionally widespread atypical oral ulcerations have been reported in lues maligna with concurrent HIV infection.<sup>133</sup>

The onset of lues maligna is characterized by a prodrome of fever, arthralgia, myalgia, headache, and photophobia. Skin lesions start as papules and evolve into pustules; within a few days the lesion centre undergoes necrosis (Figs. 36.22 and 36.23), resulting in sharply margined ulcers with an erythematous halo and a clean looking base.<sup>134</sup> The ulcers are covered with layers of crusts resembling oyster shells (Fig. 36.24). The size of the lesions varies from a few millimeters to several centimeters. In association with HIV, palatal perforation due to lues maligna has been reported.<sup>134</sup>

**Fig. 36.22:** Sharply margined necrotic ulcers with an erythematous halo in malignant syphilis. *Courtesy:* Sanjeev Gupta.

**Fig. 36.24:** The ulcers of malignant syphilis, covered with layers of crusts resembling oyster shells.

Criteria for the diagnosis of malignant syphilis proposed by Fisher et al. include compatible gross and microscopic morphology, a high titer of positivity for non-treponemal (RPR/VDRL) tests for syphilis, Jarisch–Herxheimer reaction following treatment, and dramatic response to antibiotic treatment.<sup>124</sup> Reports suggest that florid skin manifestations may be organism-depleted and demonstration of treponemes may not be possible even with sensitive techniques such as immunohistologic methods and Polymerase chain reaction (PCR).<sup>135</sup>

### RELAPSE OF SECONDARY SYPHILIS

The rash of untreated secondary syphilis lasts several weeks to 1 year. However, relapse of secondary syphilis occurs in about 20–25% of patients. The severity of relapsed disease is usually less

than the initial episode. The lesions are fewer in number and smaller in size and, unlike the initial rash, usually asymmetrical. Other rare manifestations include meningovascular neurorecurrence, periostitis, iritis, chorioretinitis, optic neuritis, and hepatitis.<sup>27</sup>

A relapse may be difficult to distinguish from re-infection.<sup>27</sup> But it is likely that the great majority of patients who have clinical or serological relapse of syphilis after standard treatment regimens for syphilis have been re-infected. Evidence of early syphilis in the current sex partner and appearance of a primary chancre at a different location support the possibility of reinfection.

Relapse can be only serological, when in the absence of clinical relapse, the reagin test becomes positive after having been negative, or shows a progressive rise in titers after a decline. This often precedes a clinical relapse. In patients with serological or clinical relapse some clinicians recommend CSF examination to exclude asymptomatic neurorecurrence. Transplacental relapse is defined as birth of a child with syphilis to an apparently cured mother. Infection of a sex partner after an apparent cure can also be evidence of a relapse.<sup>27</sup>

The diagnosis of secondary syphilis is based on positive serology for syphilis. It is also possible to demonstrate *T. pallidum* in mucocutaneous lesions by dark field microscopy. Moist lesions on mucous membranes, which are full of treponemes, are most suitable for this. However, in the mouth, non-pathogenic treponemes are present as part of normal flora and differentiation between them and *T. pallidum* is not easy. Increasingly PCR tests will be used to directly identify *T. pallidum*.

**Differential Diagnosis:** The macular rash of secondary syphilis may mimic rubella, measles, drug rash, glandular fever, and HIV seroconversion illness. A papular or papulosquamous rash may resemble psoriasis (Fig. 36.25), lichen planus, pityriasis rosea, warts, and many other dermatoses.<sup>136</sup> The vesiculopustular rash may be confused with the Von Zumbush type of pustular psoriasis and chicken pox. The differential diagnosis of nodular syphilis includes deep mycoses, leprosy, tuberculosis, sarcoidosis, and lymphoma.<sup>137,138</sup> In the anogenital area, condylomata lata may be mistaken for condylomata acuminata. Syphilitic alopecia may be misdiagnosed as alopecia areata and fungal infection of the scalp.

**Fig. 36.25:** Psoriasiform rash of secondary syphilis.

## EARLY LATENT SYPHILIS

Latent syphilis is defined as positive syphilis serology along with the absence of clinical signs and symptoms. A one year period is considered as the demarcation line between early and late latent syphilis in European (non-UK) and US guidelines and 2 years in the WHO and UK. The distinction between early and late syphilis is important for epidemiological reasons because patients in early latent stage may have relapse of secondary syphilis and thus early latency is considered as an infectious stage. Also, as the duration of infection increases, *T. pallidum* divides more slowly requiring a more prolonged duration of therapy.

Routine screening detects a substantial number of individuals with serologic evidence of syphilis without any previous history of lesions suggestive of primary or secondary syphilis.<sup>139</sup> Incidental use of antibiotics (for other diseases) probably aborts the primary and/or secondary stage(s) of the disease in some of these cases. Asymptomatic acquisition of infection is another possibility, though there is no evidence available to support it. Irrespective of RPR/VDRL titers, these patients should be considered as having late latent syphilis if the duration of the disease is not certain (see also “syphilis incognito” in the chapter on Late Syphilis). Many patients with latent syphilis have cerebrospinal fluid abnormalities suggestive of asymptomatic neurosyphilis; however, it is not clear whether all patients in whom latent syphilis is diagnosed during routine screening should be examined by lumbar puncture to guide therapeutic decisions.<sup>140</sup>

## Histopathology

The histology of the primary chancre is characterized by vascular endothelial cell proliferation and obliteration of the vascular lumen. The proliferation of pericytes is also seen. Intensive cellular infiltration is seen in specimens from older foci. This infiltrate comprises of macrophages, lymphocytes and plasma cells. For descriptive purposes, the infiltrate is classified into four categories: predominantly lymphocytic; lymphohistiocytic; predominantly histiocytic; granulomatous. Plasma cells are present in varying degrees in each category.

Treponemes are visible only by silver impregnation studies, such as the Levaditi or Warthin Starry stains.<sup>141</sup> The epidermis shows acanthosis at the margin of the lesion. Towards the centre the epidermis gradually becomes thinner and appears edematous and there is widening of rete ridges.<sup>142</sup> The ulcer surface is covered with an exudate consisting of fibrin, necrotic tissue, and polymorphonuclear leukocytes.

The predominant inflammatory cell in secondary syphilis is lymphomononuclear and the infiltrate is most intense in the papillary dermis with extension into the deeper dermis. Plasma cells are seen as focal collections around the skin appendages on the periphery of epithelioid cell granulomas (which are seen only in late lesions). However, lesions of condylomata lata show large collections of plasma cells.<sup>143</sup>

The histologic picture in secondary syphilis is not usually specific and may be misleading; it may resemble other common

diseases such as lichen planus and psoriasis. In the rash of secondary syphilis, the epidermis often shows spongiosis, parakeratosis, and acanthosis.<sup>144</sup> Exocytosis is usually seen and cells infiltrating the epidermis are either mononuclear cells or polymorphonuclear leukocytes. Collections of cells resembling Munro abscesses are also seen. In almost all lesions of secondary syphilis, the microvessel count is increased suggestive of angiogenesis.<sup>145</sup> Blood vessels show dilatation, thickening, and an increased number of large endothelial cells. Mural edema and endothelial swelling are commonly seen. A perivascular infiltrate comprising of plasma cells is commonly present. Malignant syphilis lesions may show a picture of vasculitis with fibrinoid material and necrosis of the upper dermis. Follicles and sweat glands may be surrounded by inflammatory cells. In syphilitic alopecia, keratinous plugs and a lymphoid infiltrate are seen around hair follicles.<sup>146</sup>

Treponemes are demonstrable in silver-stained preparations (Warthin Starry stain) in about 70% of the patients.<sup>147</sup> They are usually seen in the epidermis, dermis and around the walls of the capillaries. Immunoperoxidase techniques, using specific polyclonal antibodies against *T. pallidum*, has improved the sensitivity of visualization of spirochetes in paraffin-embedded tissues.<sup>148</sup> The histologic characteristics of syphilitic lymphadenitis include the constellation of follicular hyperplasia, extensive capsular and pericapsular fibrosis with chronic inflammation, sheets of plasma cells, and endarteritis.<sup>149</sup> Isolated giant cells, granulomas, and endothelial hyperplasia are also frequently seen. Silver impregnation stains sometimes detect treponemes in histologic sections from lymph nodes.

## Syphilis and HIV

A significant epidemiological association between infection with *T. pallidum* and HIV transmission has been described in a number of studies and a meta-analysis of 16 early studies estimated that syphilis increased HIV transmission four-fold.<sup>2,150,151</sup> HIV seropositive patients are at a higher risk of having serological evidence of active syphilis, and a similar increase in the serological evidence of HIV is seen with incident syphilis. Primary chancre caused by primary syphilis produces a breach in the continuity of epithelium, giving easy access for HIV to its target cells (CD4+ lymphocytes), which form a significant proportion of the infiltrating cells.

HIV-positive men who have sex with men (MSM) are disproportionately affected by syphilis and in a community-based study, syphilis incidence was almost 10 times higher in HIV-seropositive MSM than in HIV-negative MSM. This difference is largely attributable to behavioral factors and was strongly associated with unprotected anal intercourse.<sup>152</sup>

In HIV and syphilis co-infected patients the CD4 cell count may decline and viral load may increase, which may or may not revert back to baseline levels on successful treatment of syphilis.<sup>153,154</sup>

Syphilis occurring in advanced HIV disease may have atypical features, which are more common in patients with low CD4+ lymphocyte counts as may be expected from a disease where T cell mediated immunity is probably important in immunological

control.<sup>155,156</sup> Although in the majority of syphilis patients co-infected with HIV the clinical manifestations of early syphilis remain unaltered, some may present with unusual features. Healing of primary chancre may be slowed with the ulcer being more often present when secondary infection starts.<sup>84</sup> Primary chancres are more likely to be larger, multiple and painful in HIV-positive individuals.<sup>84</sup> Twenty-one cases of malignant syphilis in association with HIV have been published in medical literature.<sup>157</sup> There are some case series suggesting that a more rapid progression to neurosyphilis may occur<sup>158</sup> and a prospective study suggesting that asymptomatic neurosyphilis is commoner amongst those with HIV.<sup>159</sup> However, it seems that majority of patients have the usual course and manifestations of syphilis and atypical features are seen in only a minority.

Clinical and serological response to conventional treatment for syphilis with penicillin is usually unaltered in patients co-infected with HIV and syphilis.<sup>160,161</sup>

## Syphilis in Pregnancy

Syphilis in pregnancy may result in spontaneous abortion, stillbirth, non-immune hydrops fetalis, intrauterine growth retardation, and perinatal death, as well as serious sequelae in liveborn infected children, such as hepatosplenomegaly, cardiac manifestations, and long-term skeletal and neurological disabilities. Studies from Africa have shown a strong relationship between the incidence of stillbirths, late fetal death and mid-trimester pregnancy miscarriage, and the seroprevalence of syphilis.<sup>162–165</sup> The prevalence of syphilis seroreactivity among pregnant women varies from as low as 0.02% to as high as 12.1% in different parts of the world.<sup>166</sup> Congenital syphilis may occur when an infected woman becomes pregnant or a pregnant woman becomes infected.<sup>167</sup>

The rate of transmission to the foetus in untreated women ranges from 70% to 100% in primary and secondary syphilis, 40% in early latent syphilis, and 10% in presumed late latent syphilis.<sup>61,168</sup> Overall, half of the infants of mothers with untreated syphilis of less than 2 years duration are infected. A higher fetal morbidity and mortality occurs in untreated first trimester and second trimester infection in comparison to third trimester infection, which is more often asymptomatic.<sup>167</sup>

Transmission of syphilis may occur transplacentally to the foetus or during passage through the birth canal by contact of the newborn with a genital lesion. Transmission of syphilis to the foetus is largely dependent on the duration of the disease in the mother; the longer the interval between infection and pregnancy, the more benign is the outcome in the infant (Kassowitz law). However, this law is not absolute and the risk of transmission may be intermittent. Normal offspring may be preceded and followed by an infected infant. Moreover, recent studies have demonstrated that the possibility of fetal infection might never be eliminated and transmission of syphilis to the foetus has been documented up to 10 years after infection.<sup>169</sup> The earlier belief that infection of the foetus does not occur before 18 weeks has been challenged by studies on fetal tissues that have demonstrated

that *T. pallidum* can gain access to the fetal compartment as early as 9–10 weeks.<sup>170–172</sup>

In pregnant women, the primary lesions may be larger, more conspicuous and generally indurated because of increased vascularity in the pelvic tissue. On the cervix, there may be extensive erosions and fissuring, which can heal with a rigid scar which may interfere with dilatation of cervix at parturition.<sup>1</sup>

## Laboratory Diagnosis of Syphilis

As discussed earlier, *T. pallidum* is not an easily cultivable or stainable bacterium. Therefore other laboratory methods to diagnose syphilis in its various stages have been developed. These tests for syphilis have been divided into two broad categories:

### (i) Direct identification of *T. pallidum*:

- Direct microscopic identification of *T. pallidum* is used when lesions are present or when disease is in its early stage before the production of antibodies against *T. pallidum* develops. In this very early stage, diagnosis by serological tests is not possible. This is usually achieved by dark ground microscopy.
- Direct antigen detection tests are used for experimental purposes and in research settings.
- Nucleoside amplification techniques: The PCR is now increasingly used to diagnose syphilis and is considered the gold standard for test evaluation in early syphilis.

### (ii) Serological tests to detect IgG antibodies<sup>173</sup>:

- Non-treponemal tests—to determine disease activity
- Treponemal tests for screening and disease confirmation
- Detection of treponemal IgM antibodies to detect early infection (assays are often combined IgG/IgM tests.)

## DIRECT IDENTIFICATION OF *T. PALLIDUM*

### Dark Field Microscopy

This method is traditionally used to demonstrate *T. pallidum* in the exudate from mucocutaneous lesions in early acquired and early congenital syphilis.<sup>174</sup> This is one of the most specific and easiest methods for diagnosis of infectious syphilis when lesions are present. By this method, primary syphilis can be diagnosed weeks before the appearance of a detectable serological response.

Treponemes cannot be observed with ordinary light microscopy because of their narrow width. In dark field microscopy a dark field condenser allows the light rays to strike the object in the field at an oblique angle so that no direct light, but only light rays that are reflected from the object enter the microscope objective. This gives the object a luminous appearance against a black background.<sup>175,176</sup>

### Specimen Collection

The lesion is cleaned gently with a saline soaked gauze swab and then squeezed with the index finger and thumb to produce a serous exudate. Contamination with blood should be avoided as

it affects the sensitivity of the test. The exudate is then transferred directly to a glass slide by pressing it on the lesion. A drop of normal saline can be added to the exudate to make the material homogenous. The specimen should immediately be examined as any delay reduces the motility of the treponemes.

If there are no mucocutaneous lesions, or the patient has applied antiseptic cream on the chancre, the material can also be obtained by lymph node puncture.<sup>177</sup> The skin over the enlarged lymph node is infiltrated with 1% lidocaine for local anesthesia. The overlying skin is stretched and the lymph node is held firmly. With a disposable syringe, 0.2 mL of sterile normal saline is injected into the lymph node. The lymph node is massaged gently and fluid is aspirated and expressed on a glass slide.<sup>27</sup>

Amniotic fluid obtained by amniocentesis can also be examined by dark field microscopy for treponemes in pregnant women suspected to have early syphilis.<sup>178</sup> Non-pathogenic treponemes are part of normal flora in the oral cavity, therefore dark field microscopy is not recommended for the lesions in the oral cavity.

*T. pallidum* in dark field microscopy is identified from its typical morphology and characteristic movements. Organisms easily confused with *T. pallidum* are *T. refringes*, *T. denticola*, and *T. phagedenis* (Reiter treponeme). They usually do not inhabit the genitalia. *T. pallidum* is distinguished from other treponemes by the tightness of spirals and characteristic corkscrew movements.<sup>173</sup> *T. pallidum* has 6–14 regularly wound coils. The characteristic motion of *T. pallidum* is a slow, deliberate, forward and backward movement, rotation on its long axis, soft bending, and twisting or undulation of the organism from side to side. In contrast, non-pathogenic mucosal treponemes are often irregularly coiled, may be longer and thicker than *T. pallidum*, and lack characteristic motility. *T. pallidum* cannot be differentiated by dark field microscopy from other pathogenic species causing yaws, pinta and endemic syphilis.

However, despite its usefulness as a point-of-care test and its good sensitivity and specificity in expert hands dark ground microscopy has a number of important flaws. It is time consuming, highly dependent on operator experience and training, dependent on well-maintained specialist equipment and its use is therefore confined to specialist centers.

### Direct Fluorescent Antibody– Treponema Pallidum (DFA–TP)

This test is more specific and more sensitive than dark field microscopy and differentiates pathogenic treponemes from non-pathogenic ones. Samples from the oral mucosa can also be examined by this method. Another advantage is that the slides need not be examined immediately and may be sent to a laboratory. However, this test cannot differentiate *T. pallidum subsp. pallidum* from other subspecies of *T. pallidum*. Recently, monoclonal antibody to *T. pallidum* has been used that recognizes an antigenic determinant present only on pathogenic *T. pallidum* but not on non-pathogenic commensal treponemes. The method for sample

collection for DFA-TP is the same as described for dark field microscopy. The slide is air dried and fixed with either acetone for 10 minutes or 100% methanol for 10 seconds. Alternatively, the slide can be heated gently. The smear is stained with fluorescein-labelled anti-*T. pallidum* globulin. After incubation and washing, the slides are examined under the fluorescent microscope. This method can also be used to examine tissue sections of the biopsy from lesions of early syphilis.

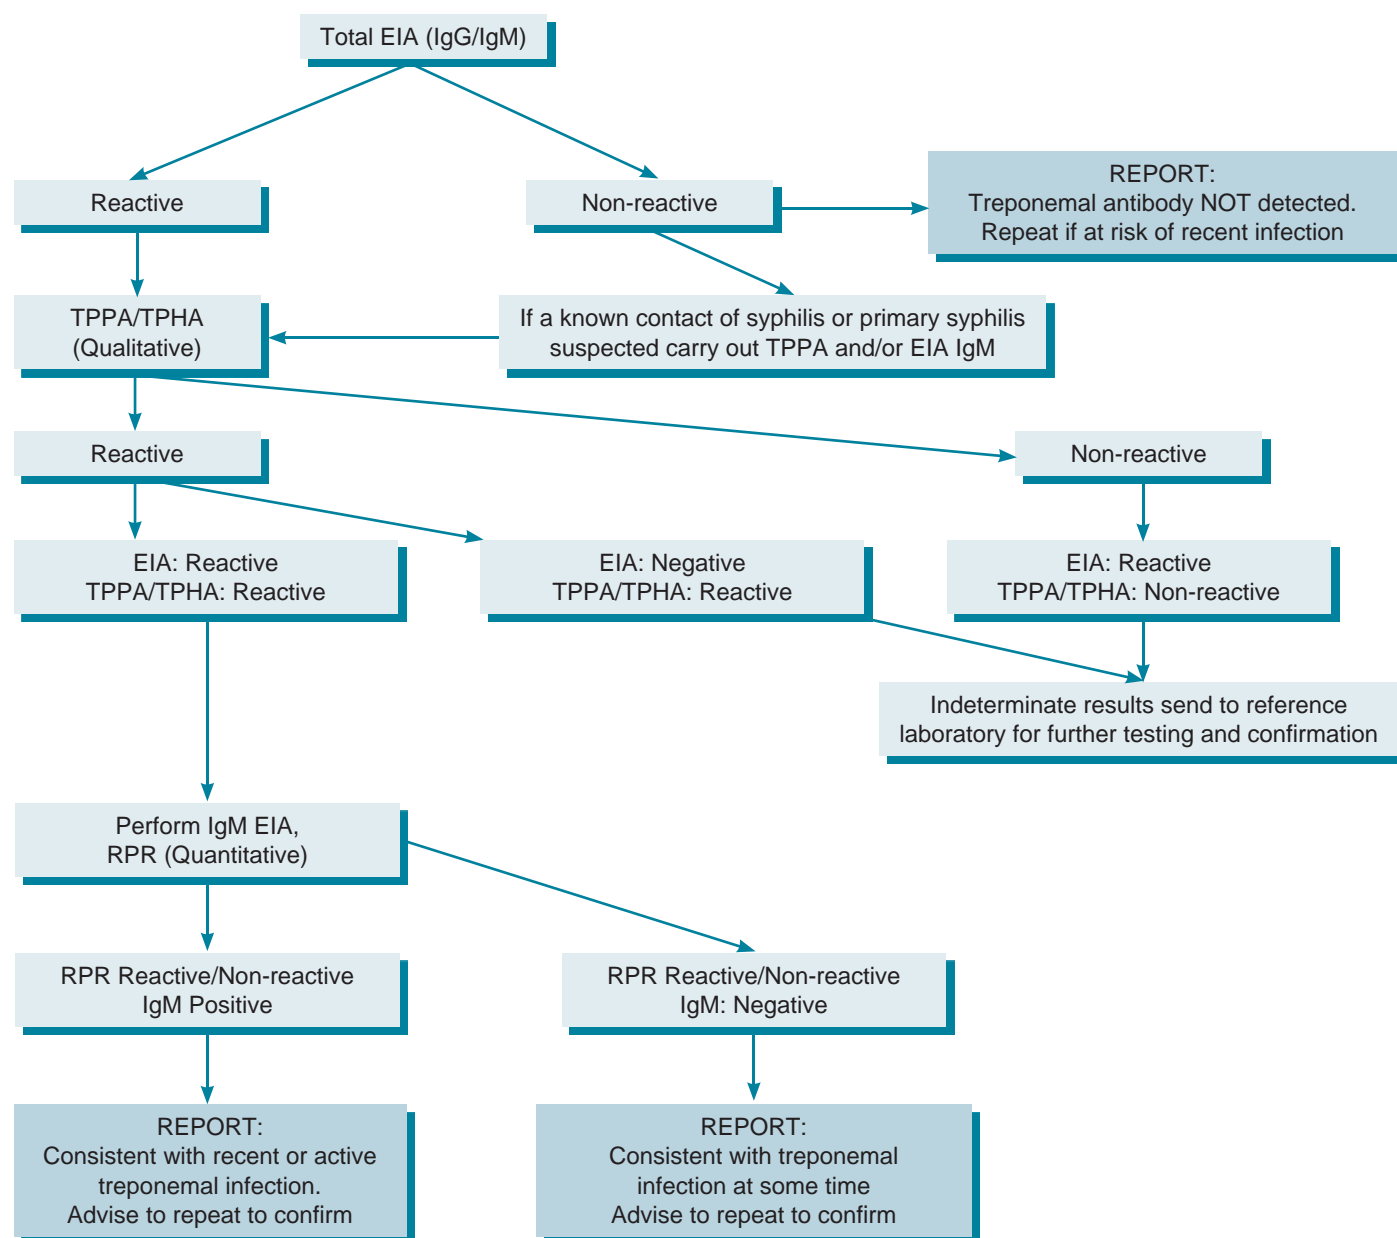

However, despite the utility of this method it is likely that in the future direct identification of *T. pallidum* will be undertaken using nucleoside amplification techniques.

### Polymerase Chain Reaction

The PCR is becoming increasingly established as the investigation of choice for identifying *T. pallidum* from the lesions of early syphilis.<sup>179,180</sup> A number of well-preserved DNA sequences (particularly DNA polymerase gene *polA*) have been identified that are specific for *T. pallidum* and do not appear to be found in other treponemes.<sup>181,182</sup> Assays based on these primers have been shown to be sensitive and specific in the diagnosis of early syphilis and will be increasingly used in the diagnosis of patients presenting with genital ulcers.<sup>182–184</sup> A number of multiplex PCR assays has also been developed for the investigation of genital ulcer disease which allow for the simultaneous detection of *T. pallidum*, *Haemophilus ducreyi* and herpes simplex virus types 1 and 2.<sup>185</sup>

### SEROLOGICAL TESTS FOR SYPHILIS

Unlike most other bacteria, *T. pallidum* cannot be readily sustained in cultures and, in the latent stage of infection, lesions are not present for direct isolation of the pathogen. Therefore serology plays an important role in the diagnosis of *T. pallidum*. *T. pallidum* infection produces antibodies to more than 20 different polypeptide antigens.<sup>186</sup> Specific anti-*T. pallidum* IgM antibodies develop during the second week of infection. IgG antibody response begins around the fourth week after infection and usually persists. Treatment causes a generalized loss of antibodies; however, IgG at a low level usually remains detectable.<sup>186</sup> An ideal serological test should have high sensitivity and specificity. In addition, it should be suitable for treatment monitoring and should give a negative result on successful therapy to allow a clear-cut diagnosis of reinfection. Such an ideal test is not yet available, however by using the different but complementary characteristics of specific and non-specific treponemal tests a diagnosis of syphilis and a serological assessment of disease activity, treatment response and re-infection can be made. Sensitive tests should be used for screening and a positive screening test should always be confirmed by further testing.<sup>187</sup> Treponemal tests are usually used for screening. If resources are available a positive test should be confirmed by a second different treponemal test. A non-treponemal serological test should then be undertaken to assess disease activity and assess treatment response. Fig. 36.26 shows an algorithm for syphilis serology developed by the Health Protection Agency in the UK.

**Fig. 36.26:** HPA testing algorithm.<sup>209,210,214</sup> Adapted from Serological Diagnosis of Syphilis, Standards Unit, Evaluation and Standards Laboratory, 2007. Health Protection Agency, UK.

Rapid, cheap, sensitive and specific point-of-care syphilis tests are becoming increasingly available. These will have a vital role in screening for syphilis in out reach and resource poor environments. At present these are mostly treponemal tests but non-treponemal point-of-care tests are now being developed.<sup>188</sup> The sensitivity of these tests has been found to be high in resource limited clinical settings.<sup>189</sup>

### Treponemal (Specific) Tests

In these tests entire *T. pallidum* or its fragments are used as the antigen to detect antibodies directed against treponemal cellular components. These tests are now increasingly used as

screening tests for syphilis particularly the newer EIA IgG/IgM tests.<sup>190,191</sup>

Treponemal tests become reactive before non-treponemal tests. However, unlike non-treponemal tests, these tests remain reactive for many years (often lifelong) in spite of adequate therapy; therefore, cannot be used for monitoring purposes. False positive results can occur and for that reason an isolated positive EIA or other treponemal test should be treated with caution.

The most commonly used treponemal tests are the EIA tests and the *T. pallidum* particle agglutination assay (TPPA) but tests include the *Treponema pallidum* immobilization (TPI) test, the serum fluorescent treponemal antibody absorption test (FTA-Abs), and the *Treponema pallidum* hemagglutination assay (TPHA).

The development of sensitive and specific enzyme-linked immunosorbent assays (EIA) has been an important development in the diagnosis of syphilis over the past 10 years. Most commercial tests use Nichols strain of *T. pallidum* as antigen. They can be automated, usually become positive within 3 weeks of acquiring syphilis and are becoming increasingly inexpensive. In many parts of the world they are becoming established as the screening test of choice.<sup>192</sup>

The *T. pallidum* immobilization test requires viable virulent *T. pallidum* (Nichols strain) grown in rabbit testes. It is based on the ability of patient antibody and complement to immobilize living treponemes, as observed by dark field microscopy. The test is complicated, technically difficult, time-consuming, expensive, and is now rarely used.

In the fluorescent treponemal antibody absorption test (FTA-Abs) *Treponema pallidum subsp. pallidum* (Nichols strain) is fixed on glass slides. The patient's serum is diluted in an extract from cultures of the non-pathogenic Reiter treponeme to remove non-specific treponemal antibodies, which are present in some individuals in response to non-pathogenic treponemes. This serum is then added to the glass slide. If it contains antibody, it coats the treponemes. Then FITC-labelled anti-human immunoglobulin is added to the slide that combines with the patient's antibody attached to *T. pallidum*. The slide is examined under a fluorescent microscope. Before the development of the more sensitive generation of IgG/IgM EIA tests the FTA-Abs test was the first test to become positive in primary syphilis and had an important role to play in the diagnosis of early disease. However, it is relatively expensive to undertake, cannot be automated, and is prone to false positives when used for screening so is increasingly being relegated to being a confirmatory test used only in cases of diagnostic uncertainty.

The *Treponema pallidum* particle agglutination assay (TPPA), the *Treponema pallidum* hemagglutination (TPHA) test and the microhemagglutination *T. pallidum* test (MHA-TP) test are easier to perform than the FTA-Abs and are suitable for testing a large number of samples. The antigen used in this procedure is ultrasonicated material from the Nichols strain of *T. pallidum* absorbed onto the surface of microparticles (TPPA) or formalinized, tanned sheep erythrocytes (TPHA, MHA-TP). As in the FTA-Abs test, the patient's serum is first diluted in sorbent to remove non-specific treponemal antibodies. The serum is then placed in a microtiter plate and if antibodies are present in the serum, they react with the particles or sheep erythrocytes to agglutinate them.

Reactive results are shown by an agglutinated particle spot or smooth mat of cells covering the entire bottom of a well. Non-reactive results show a definite compact red button in the centre of the well, with or without a very small hole in the centre. The TPPA is increasingly used as the treponemal test of choice to confirm positive EIA tests as it is easier to automate and becomes positive earlier in the course of primary infection. It is almost always positive before the VDRL/RPR test.<sup>191</sup>

Detection of Treponemal IgM Antibodies is used by some clinicians to diagnose early infection and assess disease activity.

However, the emergence of combined IgG/IgM screening tests is reducing their utility in routine practice. IgM antibodies against *T. pallidum* appear in serum toward the end of the second week of infection, about 2 weeks before the detectable IgG response. Unlike the IgG antibody response, which persists years after adequate treatment, the IgM antibodies decline gradually and disappear usually within 6 months (range: 3–24 months, depending on the stage of infection). Thus specific IgM antibodies have been considered as indicators of active syphilis. Detection of IgM antibodies is of great diagnostic significance when congenital syphilis is suspected and may be useful if reinfection is being considered.<sup>174</sup> The molecular size of IgM prevents it from passing the placental and blood-brain barriers, while IgG antibodies freely cross these two barriers. Therefore, presence of IgG antibody in the newborn or in CSF may not be an indicator of congenital syphilis or neurosyphilis, respectively, while presence of specific IgM indicates an active infection.

Increasingly combined IgG/IgM EIA tests are being used for syphilis screening.

### Non-treponemal (Non-specific) Tests

The two most commonly available non-treponemal tests are the Venereal Disease Research Laboratory (VDRL) test and Rapid Plasma Reagin (RPR) test. Both tests have the same standardized antigen comprising of lecithin, cholesterol, and purified cardiolipin (a component of mammalian cell membranes) to detect antibody against cardiolipin. The tests have similar sensitivity and specificity but the RPR is becoming increasingly used because of the wider availability of reagents and simpler reading protocol.

The VDRL slide test has to be read using a microscope. The test is performed on serum heated at 56°C for 30 minutes. Serum and antigen are mixed within a ring on a glass slide by rotating it mechanically and results are read in a microscope at 100× magnification. If anticardiolipin antibodies are present, the antigen rods aggregate to form clumps. A quantitative test can be performed using serial dilutions of the serum.

RPR test can be read visually (macroscopically) because of the presence of a colored substance in the antigen preparation. It is performed on plastic coated cards onto which circles have been imprinted. Standardized amounts of undiluted serum and stabilized antigen suspension containing charcoal particles are mixed within the circles and spread over it.<sup>187</sup> To perform quantitatively, serially diluted serum is mixed with the antigen. The card is rotated at 100 rpm for 8 minutes. Presence of anticardiolipin antibodies produces flocculation of charcoal particles, which is classified as a positive test. The RPR test has several advantages over VDRL. It can be read macroscopically because of addition of charcoal particles, the antigen used is stabilized and cards are used instead of slides.

The RPR teardrop test is a refinement of the RPR test developed for use as a screening procedure in the field, while the RPR card circle test is used in laboratories for testing large number of specimens.<sup>173</sup> Another modification of the RPR, the

**Table 36.1:** Summary of the Course and Stages of Sexually Acquired Syphilis

Infectiousness	Stages	Time, post-infection	Clinical presentations
Early or infectious syphilis	Primary	9–90 days; average 3–4 weeks	Single or multiple, painless, indurated chancre(s) at the site of inoculation
	Secondary	Few weeks to 6 average months. 6–7 weeks	Rash, fever, malaise, lymphadenopathy, condylomata lata, mucous lesions, patchy alopecia, meningitis, headache
	Early latent	≤1 year	Asymptomatic
Late or non-infectious syphilis	Late latent	>1 year	Asymptomatic
	Late benign—gumma	1–46 years, average 10–15 year;	Gummatous lesions of any organ—liver, eyes, stomach, lungs, and testes
	Cardiovascular	10–30 years	Aortic aneurysm, aortic regurgitation, coronary artery ostial stenosis
	Neurosyphilis		
	Asymptomatic	None	
	Acute syphilitic meningitis	<2 years	Headache, meningeal irritation, confusion
	Meningovascular syphilis	5–12 years	Headache, vertigo, cranial nerve palsies, acute vascular events with focal findings, personality disturbances
	General paresis	15–20 year	Insidious changes in personality and behavior, insidious onset with dementia, delusional state, fatigue, intention tremors, loss of tone of facial muscles
	Tabes dorsalis	20–25 years	Lightening pains, dysuria, ataxia, Argyll Robertson pupil, areflexia, loss of proprioception, Charcot joints

toluidine red unheated serum test (TRUST), uses paint pigment toner toluidine red particles in place of charcoal particles.<sup>172</sup> An indirect enzyme-linked immunosorbent assay (ELISA) test has also been introduced using the VDRL test antigen.<sup>173</sup>

As the antigen used in non-treponemal tests is a component of all mammalian cell membranes, the damage to tissues caused by infection, immunization, pregnancy, age-related changes, or autoimmune diseases can result into false positive non-treponemal test results.<sup>18,193–196</sup> The reactivity in such cases is usually only in low dilutions (<1:8); however, in exceptional cases, false reactivity in very high titers (up to 1:256) has been reported.<sup>195</sup> The false reactivity can be acute (of <6 months duration) or chronic (of >6 months duration) (see Table 36.1).

However, as treponemal tests are increasingly used for syphilis screening an isolated positive non-treponemal test is becoming more unusual.

The prozone phenomenon is an immunological event seen with non-treponemal tests, which are based on antigen-antibody interaction. An agglutination or precipitation reaction will be positive depending on several factors that determine the size and solubility of the immune complexes formed *in vitro*. The optimal ratio of antigen to antibody yields an insoluble precipitate that is visible in a positive test. The “zone of equivalence” defines this optimal ratio. In the zone of antibody or antigen excess (prozone and postzone, respectively), false negative test results will occur.<sup>197</sup> It is present in 1% to 2% of serum samples from patients with syphilis and is unusual in non-HIV seropositive patients with syphilis, ranging from 0% to 0.4%. False negative non-treponemal tests can occur in patients with titers <1:4 dilutions, if the blood samples are stored at a cold temperature (4°C) before testing. An appropriate temperature for storage of blood samples is 27°C.

## Laboratory Diagnosis of Syphilis in Various Stages

### PRIMARY SYPHILIS

A presumptive diagnosis of primary syphilis is based on the presence of a chancre and a preceding history of sexual contact within the last 3 months. In early stages, when serology is still negative, detection of treponemes in the serous exudate from the chancre by dark field microscopy or PCR or DFA–TP confirms the diagnosis.

Humoral antibody response to *T. pallidum* is detectable by non-treponemal or treponemal serological tests only 1–4 weeks after the chancre has formed and non-treponemal tests (RPR/VDRL) have a sensitivity of 70–90% in primary syphilis. The combined IgG/IgM tests have a reported sensitivity in primary syphilis of up to 96% and the TPPA is reported to have sensitivity of up to 94% in primary syphilis.<sup>190,191</sup>

### SECONDARY SYPHILIS

All serological tests are positive at this stage and sensitivity for all tests approaches 100%; however, in 1–2% of patients, false negative non-treponemal tests can occur due to prozone phenomenon (see above). A presumptive diagnosis is based on the presence of typical rash and reactive non-treponemal tests in a titer greater than 1:8 in a patient with no previous history of syphilis. If a past history of syphilis is present then the criteria should be a four-fold rise in the titer. When the titer of non-treponemal tests is less than 1:8, the test should be repeated and a treponemal test should also be performed. Reactivity in dual testing (both non-treponemal and treponemal) is confirmatory.

Treponemes can be identified in lesions by dark field microscopy or PCR and that is also confirmatory.

### LATENT SYPHILIS

As the lesions are not present in latent syphilis, the treponemes cannot be detected for a definitive diagnosis. All serological tests are reactive in early latency. However, the reactivity to non-treponemal tests decreases with the increasing duration of latency, and in approximately 30% patients with late latent or late syphilis, VDRL/RPR tests are negative.<sup>186</sup> The sensitivity of treponemal tests in late latent syphilis varies from 97% to 100%. Most of the patients with latent syphilis are diagnosed presumptively on the basis of reactive syphilis serology during screening.

### Serological Tests for Screening

At most centres, the screening for syphilis is a two step process; first, testing serum with a treponemal test (usually an EIA test) and second, confirming reactive samples with a second treponemal test (usually a TPPA or TPHA test) and undertaking non-treponemal (RPR or VDRL) testing. A modified UK testing algorithm is shown in Fig. 36.26.

In resource-limited settings, the RPR remains a useful test for screening as it is easy to perform, inexpensive and less resource intensive. It can also provide a point-of-care test result.

Routine screening for syphilis is done in many settings, for example, pregnant women, HIV clinic attendees, hospitalized patients, STI clinic attendees and blood and tissue donation.

In many countries, six-monthly syphilis serology is included in the monitoring of HIV seropositive individuals.<sup>198</sup> In areas with an outbreak of syphilis, an increased surveillance in HIV infected persons at 3-month intervals is recommended to detect syphilis at an earlier stage. This reduces the duration of infectiousness.<sup>199</sup>

In most countries, routine antenatal screening for syphilis is recommended to prevent congenital syphilis. As the transmission to the foetus usually takes place at 4 months of gestation, early antenatal serological screening and treatment prevents most cases.<sup>200–202</sup> The WHO has recommended that serological screening tests should be performed on all pregnant women at their first antenatal care visit and this should be repeated early in the third trimester. In areas with a high prevalence of syphilis, the CDC in the US has recommended re-screening in the third trimester and again at the time of delivery to detect new infections during pregnancy. In one study from South Africa, seroconversion rate for syphilis at the time of delivery was 2.7%.<sup>203</sup> Transmission to the foetus from mothers who acquire syphilis during pregnancy is almost certain and can only be recognized by repeat screening in the third trimester.<sup>204</sup>

### Treatment

The primary goals of therapy are to prevent transmission and avoid late complications of syphilis.<sup>18</sup> To achieve these, a therapeutic level of antimicrobials needs to be achieved in the serum and in the CSF if there is clinical evidence of CNS involvement.

**Table 36.2:** The Standard Treatment Recommendations for Infectious Syphilis<sup>13,16,191–194</sup>

Stage	Standard treatment	Alternatives
Primary, secondary, and early latent syphilis	Benzathine penicillin 2.4 mega units intramuscularly as a single dose or aqueous procaine penicillin 600,000 units intramuscularly per day for 10 days	Doxycycline 100 mg orally twice a day for 14 days
Late latent syphilis	Benzathine penicillin 2.4 mega units intramuscularly weekly over two weeks (three injections days 0,7,14) or Aqueous procaine penicillin 900,000 units intramuscularly per day for 17 days	Doxycycline 100 mg orally twice a day for 28 days
Neurosyphilis	Aqueous procaine penicillin 1.8–2.4 mega units intramuscularly per day for 17 days combined with probenecid 500 mg four times per day or intravenous benzylpenicillin 3–4 MIU 4 hourly for 14 days	Doxycycline 200 mg orally twice daily for 28 days

The standard treatment recommendations for infectious syphilis and the recommendations for complicated early syphilis and early syphilis in pregnancy are shown in Table 36.2.<sup>16,19,205–208</sup>

### PENICILLIN

Parenteral penicillin therapy remains the cornerstone of syphilis treatment and is the only treatment for which long-term follow-up data is available.<sup>1,201,203,208</sup>

A serum level of penicillin greater than 0.018 mg/L is considered as treponemocidal and in early syphilis *T. pallidum* divides every 30–33 hours.<sup>206,207</sup> Therefore a therapeutic level of penicillin maintained for 7–10 days is considered sufficient for curative treatment. In late syphilis, treponemes divide more slowly as supported by the studies that show the persistence of viable treponemes in lymph nodes of patients with latent syphilis and experimentally infected rabbits after doses of penicillin that are curative for early syphilis.<sup>206,207</sup> Therefore the therapeutic levels of penicillin in serum are required for a much longer duration in late syphilis than that are required for early syphilis.<sup>208</sup> Penicillin G is the drug of choice for all stages of syphilis. Parenterally administered penicillin G is preferred as it provides guaranteed bioavailability and is a directly observed therapy (DOT).<sup>209,210</sup> In general a depot preparation of a long-acting penicillin is preferred for the treatment of syphilis because they are easy to administer, are inexpensive, and do not require frequent re-administration.<sup>18</sup> Benzathine penicillin offers an effective and simplified treatment. Its blood levels remain persistent at a low, but treponemocidal, level for 18–25 days. Its reconstitution with lidocaine reduces the discomfort associated with injection.<sup>168</sup>

The concentration of penicillin in CSF is less than 10% of that of the serum level. Mohr et al.<sup>211</sup> found that 12 of 12

patients treated with benzathine penicillin had no detectable penicillin<sup>212</sup> in the CSF. Tramont reported isolation of *T. pallidum* from the CSF of two asymptomatic adult patients treated with recommended doses of penicillin. CSF abnormalities have been detected in nearly 30% of patients with primary and secondary syphilis.<sup>213</sup> None of the intramuscular penicillin treatment regimens consistently produce treponemicidal concentrations in CSF. However, there is no evidence that in patients with early syphilis, persistent treponemes in the CNS after benzathine penicillin G therapy cause relapse. Thus a single injection of benzathine penicillin remains the treatment of choice for all patients with early syphilis despite evidence of early invasion of the CNS by *T. pallidum* in some patients.<sup>159,114</sup>

Failure to cure early syphilis with recommended doses of penicillin has been reported.<sup>215,216</sup> However, in these cases the extended re-treatment with penicillin resulted in cure, so it was not considered that treponemes were less sensitive or resistant to penicillin. Nevertheless, treatment failure with penicillin in early syphilis is extremely rare and it gives a cure rate of nearly 100% in primary and secondary syphilis.<sup>217–219</sup>

A serum amoxicillin concentration of 0.11 g/L was established as being treponemicidal in a rabbit model with orchitis. Seventeen patients treated with amoxicillin 3 g twice a day and probenecid 0.5 g twice a day given for 3 weeks has been found to be a good alternative to injectable penicillin in HIV infected patients with syphilis, as it achieves a high concentration in the CSF. However, the gastrointestinal side effects are troublesome and many patients may not complete the therapy.<sup>220</sup> Rolfs et al. compared the efficacy of a single injection of benzathine penicillin 2.4 million units with enhanced therapy comprising of a combination of a single injection of benzathine penicillin plus 2 g of amoxicillin and 500 mg of probenecid taken orally 3 times daily for 10 days in patients with primary and secondary syphilis.<sup>114</sup> They found that enhanced therapy with amoxicillin and probenecid did not improve the outcome. In a study on the efficacy of amoxicillin in 89 patients with syphilis who were HIV seronegative, the cure rates were 100% for primary and secondary syphilis, 66.7% for late syphilis, and 60% for adult congenital syphilis.<sup>221</sup>

## Allergic Reactions to Penicillin

The main hazard treatment of syphilis with penicillin is allergic reactions, most serious of which are angioedema and anaphylaxis (Type I hypersensitivity). Angioedema manifests as marked swelling of the lips, tongue, face, and periorbital tissues with or without bronchospasm and skin rash.<sup>222</sup> The clinical picture in anaphylaxis varies widely in severity but can be associated with circulatory collapse, severe hypotension, and death. In less dramatic cases, bronchoconstriction with abdominal pain, nausea, vomiting, diarrhea, extreme weakness, fall in blood pressure, and purpuric skin rash can occur in various combinations. The incidence of anaphylaxis/angioedema varies from 0.04% to 0.2% in persons treated with penicillin. However, death following these reactions is extremely rare and is estimated to be approximately 0.001%.<sup>222</sup>

A reliable history of previous adverse response to penicillin is valuable in predicting whether a patient will have an allergic reaction. A specific history for various manifestations of immediate hypersensitivity reactions, like urticaria, angioedema, anaphylactic shock, and maculopapular rash may be taken. However, the condition is over-diagnosed on the basis of history alone.<sup>222</sup>

An intradermal test for penicillin allergy may be performed using standard amounts of a mixture of a major determinant (benzylpenicilloyl polylysine) and minor determinants, e.g. benzylpenicillin itself. A positive reaction is defined as appearance of a flare and wheal reaction greater than 3 mm or more in diameter. Only about 10% of patients with a history of “penicillin allergy” show a positive reaction to intradermal test, which suggests that many who are so labeled are not, or are no longer, allergic to penicillin.<sup>223</sup> The risk of an acute systemic allergic reaction to penicillin in a person with positive skin tests is approximately 67%.<sup>224</sup> Risk of anaphylactic reaction is more in patients reactive to minor determinants than in those reactive to major determinants alone. Unfortunately it is difficult to obtain the major and minor determinants of allergy commercially and in practice penicillin allergy is usually diagnosed on history alone.<sup>178</sup>

## Desensitization to Penicillin

Patients who report penicillin allergy are usually treated with alternative antibiotics.<sup>225</sup> However, in some instances the alternative therapies are unacceptable, for example, doxycycline in pregnancy. Alternative antibiotics may also be less effective than penicillin, for example syphilis in pregnancy and in neurosyphilis, some alternative drugs (particularly macrolides) may not cross the placental and blood–brain barriers in sufficient amounts to achieve treponemicidal concentration. In such patients desensitization is recommended. This procedure consists of administering gradually increasing doses of penicillin. This results in a subclinical anaphylactic discharge and binding of all IgE, and a state of antigen-specific mast cell unresponsiveness is achieved before full doses are administered. The desensitization process can be done through the oral route or intravenous route. The former is preferred and standard desensitization protocols are illustrated in Table 36.3. It is recommended that desensitization is repeated if further courses of penicillin therapy are required.

## Management of Reactions to Penicillin

All patients receiving penicillin should be advised to stay for observation for at least 20 minutes. If an anaphylactic reaction is suspected, rapid assessment and treatment is essential. Patients with anaphylaxis require intravenous adrenaline followed by parenteral antihistamines and corticosteroids. Some individuals will require cardiopulmonary resuscitation with a particular need to maintain airway.

## Procaine Reaction

Inadvertent intravenous injection of procaine penicillin may result in the procaine reaction (also known as Hoigne syndrome

**Table 36.3:** Causes of False-positive Serological Tests for Syphilis; Listed in Alphabetical Order.<sup>13,37,189,191,218-221</sup>

Infectious causes			Non -infectious causes
Bacterial	Viral	Parasitic	
Bacterial endocarditis	Chickenpox	Malaria	Advanced cancer
Chancroid	HIV	Trypanosomiasis	Chronic liver disease
Leprosy	Infectious mononucleosis		Connective tissue disease
Leptospirosis	Measles		Intravenous drug use
Lymphogranuloma venereum	Mumps		Lymphosarcoma
<i>Mycoplasma pneumoniae</i>	Vaccinia		Multiple blood transfusions
Psittacosis	Viral hepatitis		Multiple myeloma
Relapsing fever			Old age
Rickettsial disease			Pregnancy
Scarlet fever			
Tuberculosis			

or procaine psychosis.) It occurs just after or even during administration of procaine penicillin. It is a short-lived reaction whose hallmark is a sense of “impending doom.” It usually only lasts 15–20 minutes and usually all that is required is calm reassurance. Occasionally, the patient will need resuscitation if this syndrome is associated with circulatory collapse.

## Jarisch–Herxheimer Reaction

Management of Jarisch–Herxheimer reaction has been described below.

## CEPHALOSPORINS—CEFTRIAZONE

Although there is a 10–20% cross-hypersensitivity risk for patients treated with cephalosporins who are allergic to penicillin some clinicians do recommend this therapy in patients with a history of penicillin allergy. Treatment with intramuscular ceftriaxone in early syphilis appears to be effective, but it has to be given for 5–10 days. Single dose of ceftriaxone is insufficient for cure.<sup>214</sup> Ceftriaxone has been found to be effective in patients with latent syphilis and neurosyphilis with and without HIV infection.<sup>226–229</sup> It has been shown to have good CNS penetration. The treponemicidal concentration for ceftriaxone is 0.0006 mg/ml. and levels well above this can be achieved in CSF by giving 1 g daily, although, most guidelines recommend a dose of 2 g daily if neurosyphilis is suspected. Ceftriaxone is preferred over other cephalosporins because of its longer half-life of 7 hours.<sup>227,229</sup> The drug is best given by intravenous route, as intramuscular ceftriaxone may not be an adequate treatment for neurosyphilis. Lower intramuscular doses may be given for early syphilis.

## MACROLIDES

### Erythromycin

Treatment regimens with erythromycin have not been evaluated extensively in early or late syphilis. Erythromycin has been recommended as an alternative drug for patients allergic to penicillin or for those who refuse parenteral therapy. The efficacy also depends on the compliance of the patients.

In pregnant women with early syphilis, erythromycin gives sub-optimal success rates in prevention of congenital syphilis.<sup>230</sup> There are reports of failure of erythromycin therapy in HIV infected patients with early syphilis.<sup>231</sup>

### Azithromycin

Azithromycin is a long-acting, azalide antimicrobial agent. It has a long half-life (68 hours) and can be given orally. Oral administration of azithromycin results in low but prolonged plasma levels, high intracellular concentration, and high concentrations in most tissues, including CNS.<sup>232</sup> In experimental studies, azithromycin has been found to be active *in vitro* against *T. pallidum*<sup>233</sup> as well as effective in treating syphilis in rabbits.<sup>234</sup> This has led to several studies of its use in treating patients with syphilis. In open studies, single daily doses of 500 mg azithromycin given for 7–10 days was found to be effective treatment for primary and secondary syphilis. A single dose of azithromycin 1 g has been found to be effective in the treatment of incubating syphilis in persons exposed to partners with infectious syphilis.<sup>235</sup>

A single randomized trial of azithromycin 2 g given orally as a single dose compared to single dose Benzathine penicillin for early syphilis showed good azithromycin efficacy.<sup>236</sup> However, although azithromycin as a single dose oral therapy is an attractive therapy it has not become established as a first line treatment as treatment failure is well-recognized and some strains of syphilis are intrinsically resistant to macrolide therapy due to a A2058G mutation in the 23S ribosomal RNA (rRNA) gene of *Treponema pallidum*.<sup>237,238</sup> This mutation has not been found in specimens from Madagascar.<sup>239</sup> At present azithromycin cannot be recommended in the first line of therapy in syphilis except in Sub-Saharan Africa.<sup>240</sup>

## TETRACYCLINES

Long-acting oral tetracyclines are recommended for patients with early syphilis. Tetracycline in a total dose of 24–32 g given over a period of two weeks is effective in the treatment of early syphilis. However, the drug is given orally and its efficiency depends on the compliance of the patient.

Doxycycline, 200 mg daily, orally, in two divided doses is equally effective.

Doxycycline has several advantages over traditional tetracycline. It is better absorbed, can be taken with food, requires less frequent dosing because of its longer half-life, and has better penetration to CNS because of its high lipid-solubility.<sup>241</sup> There are occasional reports of relapse in patients with early syphilis treated with adequate doses of doxycycline; however, a possibility

of reinfection could not be excluded in such patients.

A large retrospective comparative study of doxycycline 100 mg twice daily versus single dose Benzathine in the treatment of early syphilis in HIV positive<sup>242</sup> individuals showed similar efficacy in the two regimes. Doxycycline crosses the blood-brain barrier and sufficient concentration is obtained in CSF.<sup>241</sup> Tetracyclines are contraindicated in pregnancy.

### TREATMENT IN PREGNANT WOMEN

In one study, single injection of benzathine penicillin 2.4 million units showed a 98% success rate in preventing congenital syphilis in pregnant women with early syphilis and introducing an intervention of antenatal screening and single dose Benzathine penicillin has been shown to eliminate all the adverse consequences of syphilis in pregnancy.<sup>202</sup> However, the success rates in other studies have been lower than this, particularly for women treated for syphilis in the last trimester and therefore some clinicians recommend that all pregnant women with early syphilis should be treated with two injections of benzathine penicillin (2.4 million units) given one week apart.<sup>243</sup> Pregnant women with syphilis of unknown duration and late syphilis should receive three injections of Benzathine penicillin one week apart over two weeks (day 0, 7, and 14) or a 15-day course of aqueous procaine penicillin (600,000 units IM) once daily.

### TREATMENT IN HIV-POSITIVE PERSONS

There have been some reports of progression to neurosyphilis after adequate therapy of patients with early syphilis who are also co-infected with HIV.<sup>243–245</sup> This has prompted some experts to recommend CSF examination of HIV-infected patients with early syphilis at the time of presentation. These experts recommend that all such patients with CSF abnormalities should be treated for neurosyphilis. However, the results of CSF examination are difficult to interpret in HIV seropositive persons as they have a high rate of CSF abnormalities unrelated to syphilis.<sup>246</sup> Respondents of a survey of Infectious Disease experts revealed that those who treated more patients with syphilis were less likely than those who treated fewer patients with syphilis to perform a lumbar puncture for an HIV-positive patient co-infected with secondary syphilis without neurologic or ophthalmologic symptoms. Authors of the survey concluded that these findings suggest that increased experience managing syphilis may correlate with confidence that management according to established guidelines is sufficient to prevent adverse outcomes.<sup>247</sup> As discussed earlier, augmented therapy with amoxicillin and probenecid has not been found superior to the conventional therapy in these patients.<sup>114</sup> No consistent data are available on either frequency of treatment failures or of progression to neurosyphilis and other complications.<sup>248</sup> Contradictory reports exist on serological response to conventional treatment of syphilis in HIV seropositive patients, with some studies showing a similar serological response for syphilis in HIV negative and HIV positive patients, while others show a delayed or absent serological improvement in HIV

positive patients.<sup>161,246</sup> Therefore, all major treatment guidelines recommend the same treatment for patients with all stages of syphilis with HIV infection as that for patients with syphilis without concurrent HIV infection.<sup>16,19,205</sup> However, a more frequent serological and clinical follow-up (at 3, 6, 9, 12, and 24 months post-treatment) has been recommended for these patients. If during the follow-up, any patient shows a rise in the titers or relapse of signs and symptoms, then some guidelines recommend that CSF should be examined and re-treatment should be guided by the results of the CSF examination.

Likewise, some guidelines recommend that all HIV seropositive patients with late latent syphilis or latent syphilis of unknown duration should undergo CSF examination. Those with no CSF abnormalities should be treated with three injections of benzathine penicillin 2.4 million units given one week apart. US guidelines suggest that patients with CSF abnormalities need to be treated for neurosyphilis.<sup>19</sup> Some experts also recommend CSF examination 2 years after treatment of early syphilis in all HIV seropositive patients.<sup>16</sup> However, these recommendations are not supported by clinical trial evidence.

### JARISCH–HERXHEIMER (J–H) REACTION

The J–H reaction is a febrile illness that occurs within the first 24 hours of antimicrobial treatment and is commonly seen in patients with early infectious syphilis. The reaction is associated with increased circulating levels of tumor necrosis factor alpha (TNF-alpha), interleukin-6 and interleukin-8. Lysis of spirochaetes, releasing endotoxins probably contributes in its pathogenesis.

In various studies, the J–H reaction has been observed in 18.8–95% of patients with early syphilis.<sup>248–250</sup>

The J–H reaction occurs as an acute febrile illness with rigors, headache, myalgia, and rash of secondary syphilis appearing or becoming more prominent. It usually occurs between 3 and 12 hours after treatment. The reaction is important in pregnant women with syphilis in whom it may induce early labor or cause fetal distress, which however, should not prevent or delay the therapy.<sup>205</sup> A prospective study of 33 pregnant women treated with penicillin for early stage syphilis showed that most women experienced self-limited uterine contractions, decreased fetal activity, and fetal heart rate abnormalities, however there were no events of premature labor.<sup>251</sup> Complications due to J–H reaction have also been described in neurosyphilis, ocular syphilis, cardiovascular syphilis, and syphilis of the larynx because of the local edema. Because of these potential complications, some recommend a small dose of glucocorticoids (10–20 mg prednisolone) started one day before specific therapy instituted in patients with late syphilis involving CNS, heart or larynx, however, its effectiveness has never been proved. In such patients, treatment with a TNF-alpha antagonist may be more effective in suppression of inflammation and prevention of tissue destruction although the evidence for its use is currently lacking.<sup>248</sup>

Patients who are being treated for early syphilis should be warned about the possibility of the J–H reaction and should

be advised to rest take antipyretics and drink clear fluids until symptoms settle.

## MANAGEMENT OF SEX PARTNERS

CDC recommends presumptive treatment for all sex partners exposed during last 90 days irrespective of their serological status, considering that these contacts may have incubating syphilis.<sup>205</sup>

Sex partners exposed more than 90 days before should be screened and managed according to their serological status. If serology is not immediately available, then all such contacts should also be treated epidemiologically.

The treatment of choice for epidemiological treatment of syphilis is a single dose of Benzathine penicillin 2.4 MIU intramuscularly. It is likely that doxycycline 100mg twice daily for 14 days is effective for treating incubating syphilis and there is evidence that Azithromycin 1 g as a single dose is a useful treatment to prevent incubating syphilis.

## SEROLOGIC RESPONSE TO SYPHILIS TREATMENT

Patients with clinical manifestations of early syphilis (ulcers, rash, etc.) should be followed up to ensure that these have resolved with treatment. There is no ideal test of cure for syphilis available that can be carried out within days or weeks after treatment. The great majority of patients treated with standard penicillin and doxycycline based regimes for early syphilis are cured with most clinical and serological relapses being caused by re-exposure to syphilis. Patients can be re-assured that they have cured provided that therapy is fully adhered to. The goals of serological follow-up are to confirm treatment response, identify re-exposure and establish the post-treatment RPR/VDRL level from which re-infection can be determined.

In most guidelines a four-fold (two titer) RPR/VDRL titer fall by six months or earlier after treatment of early syphilis is considered an adequate treatment response.

To assess treatment, the patient is asked to return for repeat quantitative non-treponemal serologic testing (VDRL/RPR) and at 3, 6 and 12 months. When the serologic test becomes negative the patient can be discharged from care. Generally seroreversion is achieved in the majority of the patients with primary syphilis in about 12 months after treatment<sup>217</sup> and in those with secondary syphilis in about 24 months.<sup>218</sup> Talwar et al. found that at 30 months post treatment, only about 6% patients with primary syphilis and 8% patients with secondary syphilis were seroreactive.<sup>252</sup> The seroreversion is more rapid after therapy if the duration of infection is short and if the initial titer is low. Romanowski et al. observed that more than 80% patients with primary syphilis with pre-treatment titer less than 1:8 were seroreverted at 24 months, while only 20% of those with pre-treatment titer greater than 1:256 were seroreverted after that period.<sup>253</sup> For patients with secondary syphilis, these figures were 60% and 8%, respectively and those for early latent syphilis, 31% and

0%, respectively.<sup>253</sup> However, the rate of decline of high titer reactivity is more rapid after treatment than the rate of decline of lower titer reactivity.<sup>236</sup> Seroreversion may be delayed in repeat infection. As seroreversion is a slow process requiring months to years, the rate of decline is a better indicator of therapeutic response. A 4 fold (two titer) decline in the titer is considered a good therapeutic response and this should occur within 3 to 6 months after therapy in patients with primary and secondary syphilis and within 12 months in early latent syphilis. VDRL titers may not decline in patients with late syphilis and remain reactive at a low level (<1:8) for many years after adequate treatment.<sup>253</sup> There is no satisfactory monitoring test available for non-treponemal tests-negative late disease.<sup>173</sup> Patients with syphilis who are HIV positive may show less serological improvement after conventional treatment than patients with syphilis who are HIV negative. The interval between treatment and a fourfold decrease in titer may be longer in HIV positive patients than in HIV negative patients.<sup>246</sup> This difference is more pronounced in patients with pre-treatment titers of 1:32 or less.

The treponemal tests are less likely to serorevert. In one study, it was observed that treponemal tests seroreverted only in 10–15% of patients with a first episode of primary syphilis, but in none of those with latent syphilis at 24 months after adequate treatment.<sup>252</sup>

## Prevention and Control

Conventional public health methods of enhanced surveillance, screening, partner notification, as well as collaboration with community-based non-governmental organizations are important in the control and elimination of syphilis.<sup>72</sup> In spite of a decline and re-emergence of syphilis, it does not appear to cycle and therefore there is a real possibility of eliminating syphilis.<sup>254</sup>

There are no effective vaccines against syphilis. Recent developments in the identification of *T. pallidum* immunogens may prove useful for vaccine development.<sup>51</sup>

Epidemiologic/presumptive treatment of all contacts of patients who were exposed within 90 days is essential. Public education about the sequelae and prevention of syphilis and other sexually transmitted diseases is paramount in the primary prevention of the disease.<sup>60</sup> Condom use reduces the transmission of syphilis and should be promoted in high-risk groups. Routine screening for syphilis is recommended in high risk groups, like STI clinic attendees, sex workers, intravenous drug users, and HIV positive persons, and this approach has been found effective in control of the disease. Mass screening is not recommended in areas with low prevalence, as it is not cost effective. Defining the efficacy of azithromycin for early syphilis might simplify therapy. Single dose, directly observed therapy with oral azithromycin, if found efficacious for incubating syphilis and useful in early syphilis may have a pivotal role to play in the control of syphilis, dealing with the crucial issue of patient compliance and the problems of delivering parenteral penicillin in non-clinical settings.<sup>72</sup>

## Targeted Mass Treatment

In several areas with high prevalence of syphilis, health workers have tried to reduce the spread of disease by treating everyone in the targeted group even if they do not exhibit the symptoms.<sup>255</sup> Between 1952 and 1969, under a WHO and UNICEF sponsored global campaign, health workers administered single dose of penicillin to 50 million people infected with yaws in 45 countries. This program almost eradicated yaws, which reappeared in 1990s. In some areas of Indonesia, health workers regularly treat sex workers with penicillin. In North America, a few smaller mass treatment interventions have been found useful in the control of syphilis.

In California, the incidence of syphilis declined by 27% among the migrant workers and by 51% among female sex workers after such an intervention in 1976–1977. Another intervention was reported to be successful in a cocaine-related syphilis outbreak.<sup>256</sup> However, in Greenland, during the late sixties, mass treatment with penicillin, and recently, in Canada, mass treatment with oral azithromycin did not show promising results.<sup>257</sup> The problems associated with mass treatment are high cost, side effects, drug resistance, and increased susceptibility to other infections. Currently, targeted mass treatment for syphilis is not recommended. If complete coverage of high-frequency transmitters cannot be achieved and if population mobility is relatively high, a rebound increase in the prevalence of syphilis can occur in the target population.<sup>258</sup>

### Summary

Infectious syphilis remains an important cause of morbidity and mortality worldwide, and primary and secondary syphilis significantly increase the risk of transmitting and acquiring HIV. Syphilis in pregnancy is a major cause of adverse pregnancy outcomes and perinatal morbidity and mortality. Although PCR tests are being increasingly used for the diagnosis of early syphilis, the cornerstone of diagnosis remains serological tests. Parenteral penicillin is the treatment of choice.

# Late Syphilis

Ashish Sukthankar • Anne M. Rompalo

## Introduction

Natural history studies have been used to describe two broad stages of syphilis—early and late. The early stage is characterized by occurrence of primary and secondary syphilitic manifestations. Rashes of secondary syphilis are known to recur up to 2 years after infection. After this period the disease enters a prolonged asymptomatic phase when the only sign of disease is positive serological tests. Most authorities consider 2 years as a cut off between early and late syphilis.

Late syphilis begins with a continuation of the early latent phase which is termed late latent syphilis. The Oslo study of untreated syphilis in the first half of the twentieth century was pivotal to our understanding of the natural history of syphilis, especially the outcome of late latent syphilis.<sup>1</sup> Without treatment, a third of the patients would have a spontaneous cure wherein the VDRL/RPR test becomes negative and there is no recurrence of disease. A further third of patients maintain a positive VDRL/RPR test but no sign of disease. The remaining third of patients would develop signs and symptoms of late syphilis: half with benign tertiary syphilis, a quarter with cardiovascular disease and a quarter with neurosyphilis. There is some overlap among these manifestations with some patients suffering from two or even three forms of late syphilis. It should also be noted that neurosyphilis can occur at any stage of syphilis, not just the late stage, and any patient with neurological signs and symptoms who has evidence of syphilis should be evaluated for neurosyphilis regardless of stage or HIV serostatus. For the sake of discussion, neurosyphilis will also be addressed in this chapter, but also may be considered elsewhere.

In the post antibiotic era, the incidence of most forms of late syphilis have shown a steady decline to such an extent that they have been relegated to isolated case reports. The advent of HIV infection since the 1980s has renewed interest in these manifestations. Several authors have suggested that HIV positive patients are more at risk of developing neurosyphilis.

Most studies on late syphilis, especially neurosyphilis, have been hampered with significant problems such as the inability

to culture the causative organism, difficulty in interpretation of serology and hence establishing the diagnosis, difficulty in defining a cure, inaccessibility of diagnostic material such as CSF, difficulty in distinguishing between re-infection and treatment failure, complex interaction with co-infection with HIV and paucity of cases. Hence current knowledge is based on mainly old studies in the pre-antibiotic and immediate post-antibiotic era.

## Epidemiology

As mentioned earlier, most forms of late syphilis have disappeared from clinical practice. Some forms of neurosyphilis are still seen today, especially in HIV infected patients.<sup>2</sup> Approximately one-third of patients with early syphilis have central nervous system invasion, however in HIV uninfected immunocompetent patients, it is generally subclinical and treatment with 2.4 MU benzathine penicillin eliminate it in overwhelming majority of patients.<sup>3</sup> It seems that in HIV infected patients, early invasion of central nervous system (CNS) may progress to early neurosyphilis due to failure of initial control. The reported high incidence of neurosyphilis in dually infected patients may also be related to high CSF abnormality due to opportunistic infections causing diagnostic confusion.<sup>4,5</sup>

All the major population statistical reports combine the figures for late latent syphilis with those of late syphilis. Hence it is difficult to ascertain the exact incidence of late syphilis in the 21st century.<sup>6,7</sup> In the United States, in 1976, the last year in which the Centers for Disease Control and Prevention recorded the number of neurosyphilis cases separately, there were 2903 cases of neurosyphilis of a total of 71,761 reported cases of syphilis.<sup>8</sup>

This chapter will address the various stages of late syphilis in the order of their appearance in the natural history.

## Late Latent Syphilis

This stage is the continuation of the early latent syphilis. The clinical relevance of distinguishing early and late latent stage is with respect of infectiousness (early latent syphilitic patients are considered to be more infectious than those in the late latent

stage due to paucity of *Treponemes* in the latter) and duration of treatment (more prolonged course of treatment needed in the late latent stage to account for the slowly dividing *Treponemes*).

Syphilis incognito<sup>9</sup> is a subtype of latent syphilis (early or late), which runs a subclinical course from the time of infection until its diagnosis by routine serologic screening. Patients with syphilis incognito do not give a history of earlier stages of syphilis and are diagnosed on routine screening with positive treponemal serology. It is unclear whether this is because of inadequate and inadvertent antibiotic use resulting in suppression of early syphilis manifestations, due to misdiagnosis of secondary syphilitic rashes or lack of awareness of painless primary chancres in inaccessible sites such as cervix or anal canal. Stratigos et al.<sup>9</sup> reported 67.5% of 528 patients with latent syphilis to have syphilis incognito in a series from Athens.

## DIAGNOSIS OF LATE LATENT SYPHILIS

By definition, patients are asymptomatic. Diagnosis is primarily by means of treponemal serology which includes positive non-specific serological tests, that is, VDRL/RPR, usually in low titers of 1 in 8 or less, and almost universally reactive specific treponemal tests, that is, TPPA/TPHA, MHA-TP and EIA tests. These tests are dealt in more detail in the chapter on infectious syphilis. Most guidelines advocate a thorough clinical examination and a chest X-ray to rule out systemic involvement. A negative VDRL/RPR test on peripheral blood suggests that neurosyphilis is unlikely<sup>10</sup> whereas a titer of 1:32 or more may predict CSF abnormalities.<sup>11</sup> A risk-benefit analysis of patients with late latent syphilis suggests that a lumbar puncture is unnecessary in these patients.<sup>12</sup> As debated in the section on asymptomatic neurosyphilis, various forms of penicillin are able to prevent progression of these cases to overt neurosyphilis.<sup>13</sup> Hence, a lumbar puncture is only recommended in late latent syphilis if there is treatment failure. Patients with HIV co-infection are dealt in a separate section.

## Neurosyphilis

Involvement of the CNS by *T. pallidum* is one of the most dreaded complication of syphilis and case reports in the post-antibiotic era of neurosyphilis remind physicians of the seriousness of this infection. As mentioned before the rates of neurosyphilis have steadily declined over the latter half of the twentieth century.

## CLASSIFICATION

Merritt and colleagues<sup>14</sup> (modified by Swartz et al.<sup>15</sup>) classified the various forms of neurosyphilis in the pre-antibiotic era but it is important to note that there is considerable overlap of these syndromes and many patients had features of different forms of neurosyphilis. (Table 37.1)

Neurosyphilis can also be divided into early and late forms.<sup>16</sup> Early neurosyphilis is commonly associated with CSF changes and involvement of cerebral blood vessels and meninges. It occurs within weeks to a few years after infection. It can be

**Table 37.1:** Classification of Neurosyphilis<sup>14,15</sup>

Type	Percent in whom predominantly seen
<b>Asymptomatic (early and late)</b>	31
<b>Meningeal</b>	20
Acute syphilitic meningitis	6
Meningovascular (including deafness)	11
Cerebral	Rare
Spinal	3
<b>Parenchymatous</b>	48
General paresis	12
Tabes dorsalis	30
Taboparesis (mixed)	3
Optic atrophy	3
<b>Gumma</b>	1
Cerebral	Rare
Spinal	Rare
Total	100

asymptomatic, may present as meningitis, with or without cranial nerve or eye involvement, as meningovascular disease or stroke. Late neurosyphilis mainly involves the meninges and brain or spinal cord parenchyma. This form is now extremely rare and occurs years to decades after primary infection. Manifestations of this stage include general paresis and tabes dorsalis.

## PATHOLOGY

There is evidence that *Treponemes* invade the CNS at a very early stage. CSF abnormalities were noted in 13% of patients with primary syphilis and 25–40% of patients with untreated secondary syphilis.<sup>17,18</sup> Without treatment, this invasion may resolve spontaneously, lead to asymptomatic syphilitic meningitis or develop into symptomatic acute syphilitic meningitis. The latter two conditions, if left untreated, may progress to meningovascular syphilis 5–12 years later, or tabes or paresis 18–25 years later. However, in many patients co-infected with HIV, neurosyphilis has been reported to occur at the early stage. This may be due to inability of the CNS to control the initial invasion by *Treponemes*.<sup>4</sup>

Acute syphilitic meningitis is associated with an inflammatory process involving the meninges and ependyma. A meningeal infiltrate of lymphocytes and plasma cells is seen around blood vessels. A prolonged inflammatory process results in fibroblastic organization leading to obstruction of CSF flow and hydrocephalus. Cranial nerves are affected due to compression by basilar exudates and fibrous organization. Third nerve involvement is commonly a result of raised intracranial pressure. Endarteritis of cerebral arteries associated with meningitis is responsible for the vascular association in the form of seizures and cerebral infarction/strokes.

Cerebrovascular syphilis shows the characteristic changes of endarteritis with perivascular infiltration with lymphocytes and plasma cells. Damage to the adventitia and media of medium to large-sized arteries, which leads to sub-intimal fibroblastic proliferation and subsequent luminal obliteration, results in cerebral infarction.

### EARLY ASYMPTOMATIC NEUROSYPHILIS

Abnormal CSF characterizes this stage and is difficult to diagnose as the patient is asymptomatic. Lumbar puncture is not advocated in early syphilis in the absence of symptoms and hence most patients with this condition will remain undiagnosed. However, the rarity of progression to overt neurosyphilis in the penicillin era indicates that treatment with antibiotics, whether intentional or not, results in complete resolution of these CSF abnormalities. The classic abnormalities described are 10–100 WBC/cm<sup>3</sup> which are predominantly lymphocytes, a protein of 50–100 mg/dl and a positive VDRL/RPR test in 50% of cases. The frequency of abnormal CSF findings increases until 12 to 18 months after initial infection following which there is a steady decline over many years with only 6.3% showing CSF changes at 20 years after infection in one report.<sup>19</sup> However, risk of symptomatic neurosyphilis increases in those patients with persistent CSF abnormalities. Patients with CSF changes at more than 5 years after infection developed neurologic disease in 87% of cases who had no treatment.<sup>20</sup>

Diagnostic significance of abnormal CSF findings in asymptomatic patients co-infected with HIV is unknown. CSF WBC may be elevated in these patients due to opportunistic infections or without any known cause; however, a CSF WBC greater than 20 appears to be a specific and sensitive criteria for the diagnosis of neurosyphilis in such a situation.<sup>21</sup> The risk of neurosyphilis is more in dually infected patients with CD4 count less than 350/μL and RPR titers of 1:32 or more.<sup>22</sup> Currently, CDC does not recommend CSF examination in early syphilis patients co-infected with HIV who have no CNS symptoms.<sup>23</sup>

### ACUTE SYPHILITIC MENINGITIS

According to a Merritt and Moore<sup>24</sup> report in the pre-antibiotic era, acute syphilitic meningitis is the first clinical manifestation of syphilis in a quarter of patients. The incubation period is less than 1 year and hence some patients may have a secondary syphilitic rash at the time of presentation. Symptoms of meningitis include acute or subacute onset of headache, nausea and vomiting associated with neck stiffness. It can present as cranial nerve palsies or with signs of increased intracranial pressure. Basilar meningitis commonly presents with asymmetric involvement of multiple cranial nerves, especially third, sixth, seventh, and eighth. Sensorineural deafness was seen in 20% of cases and may be preceded by tinnitus. The deafness is rapidly progressive with loss of higher frequencies. In isolated eighth nerve palsy, the CSF may be normal and there is no associated vestibular involvement.

Increased intracranial pressure resulting in acute syphilitic hydrocephalus was seen in a third of syphilitic meningitis cases in the pre-antibiotic era. This usually occurred in the first year of infection but has been reported up to 6 years after infection.

### Investigations

Both nonspecific and specific treponemal serological tests are positive in most patients. There is elevated CSF pressure on lumbar puncture and CSF shows mononuclear pleocytosis of 10–200 cells/cm<sup>3</sup>, raised CSF protein of up to 200 mg/dl, reduced glucose and elevated globulin level. The CSF VDRL/RPR is positive in a majority of cases.

### Differential Diagnosis

Lymphocytic meningitis can be caused by enteroviruses, *Leptospira*, *Borrelia* (Lyme disease), mycobacteria, or fungi. Use of imaging techniques in addition to specific serology and PCR tests would help to differentiate between these conditions.

### MENINGOVASCULAR SYPHILIS

This may affect the cerebrum or the spinal cord.

### CEREBROVASCULAR SYPHILIS

Infarction secondary to endarteritis is the primary pathology of cerebrovascular syphilis. It may affect any part of the CNS and invariably results from chronic meningitis described earlier. These manifestations commonly occur about 5–12 years after initial infection and affect the 30–50 year age group. It may be accompanied by symptoms of general paresis or tabes. Occasionally Argyll Robertson pupils may be present even in the absence of parenchymal involvement.

Focal neurological syndromes are the hallmark of this condition with most patients presenting with strokes (11.1%) and seizures (24.2%) as reported in a series of 241 patients from Virginia.<sup>25</sup> The most common artery involved is the middle cerebral artery but involvement of other arteries like anterior cerebral, posterior cerebral, basilar and posterior inferior cerebellar arteries is reported.<sup>15</sup> Although the syphilitic strokes are similar to arteriosclerotic thrombotic lesions, syphilitic thrombosis often affects the smaller branches resulting in less extensive infarcts. The onset is sudden in half the patients but in the other half may be preceded by symptoms of headache, dizziness, insomnia, and memory loss or mood disturbances over weeks or months. Personality and behavioral changes suggestive of general paresis may precede the stroke/seizures causing diagnostic confusion.

### Investigations

Treponemal serology is positive and CSF VDRL/RPR is positive in most cases. CSF examination shows pleocytosis with increased protein. “Beading” and diffuse irregularity of arteries on angiography, especially affecting anterior and middle cerebral

arteries is commonly seen.<sup>15,26</sup> The areas of arterial narrowing in syphilis are longer and smoother compared to that seen in arteriosclerosis. Neuroimaging confirm areas of ischemia or infarctions with low density areas on CT and hyperintense areas on T2 weighted MR scans.<sup>26</sup>

## Differential Diagnosis

Cerebrovascular accidents (CVA) in young adults should raise suspicion of cerebrovascular syphilis, especially normotensive patients with no other risk factor for thromboembolic disease. Diagnosis in older patients is difficult as they are at risk of other causes of CVA, such as atherosclerosis. History of untreated or partially treated syphilis, positive serological tests for syphilis and CSF examination helps in establishing the diagnosis.

Differential diagnosis includes causes of stroke, such as hypertension, atherosclerosis, cerebral thromboembolism, and various types of cerebral vasculitis.

## MENINGOVASCULAR SYPHILIS OF SPINAL CORD

Spinal syphilis was rare (3% in Merritt's series<sup>14</sup>) before the advent of penicillin and has become even rarer since. The spinal cord is affected in a similar manner as the brain, with extension of the meningeal inflammation leading to either parenchymal changes or vascular involvement or both. Syphilitic meningomyelitis is the most common form whilst, uncommonly, vascular thrombosis leads to acute syphilitic transverse myelitis.<sup>27</sup>

Syphilitic meningomyelitis presents 20–25 years after infection with a gradual onset weakness or paraesthesia of the legs, developing into paraparesis or asymmetric paraplegia.<sup>8</sup> Upper motor neurone involvement leads to classical signs of spastic paraparesis with hyper-reflexia, ankle clonus, absent abdominal reflexes and extensor plantar reflexes. Dorsal column involvement leads to loss of position and vibration sense in the lower limbs. The clinical picture may overlap with that of tabes or general paresis. Spinal vascular syphilis presents acutely similar to complete or incomplete transection of the spinal cord, usually at the thoracic level. Abrupt flaccid paraplegia, a clear sensory level on the trunk and urinary retention are classic findings. Prognosis is poor as there is little functional recovery with treatment.

## Investigations

Blood and CSF pictures are similar to that of cerebrovascular syphilis. Imaging would be useful but paucity of recent cases means there is very little literature on the subject.

## Differential Diagnosis

Multiple sclerosis and subacute combined degeneration should be excluded in patients with syphilitic meningomyelitis. Causes of acute transverse myelitis must be excluded in patients with acute onset flaccid paraplegia. Peripheral blood and CSF serology are useful to establish diagnosis.

## PARENCHYMATOUS NEUROSYPHILIS

General Paresis of the Insane (syn. Paretic neurosyphilis, dementia paralytica, general paresis).

Direct invasion of the cerebral parenchyma by Treponemes results in a meningo-encephalitis which is characterized by a clinical syndrome termed General Paresis of the Insane (GPI). It is a chronic progressive condition with an incubation period of 3–30 years. Males are more often affected than females.

Most patients present with gradual onset of symptoms while some patients may present acutely. Early symptoms are non-specific (irritability, fatigability, depression, impaired concentration, headaches, and insomnia) while more specific psychiatric symptoms appear later (impaired judgment and insight, depression or elation, confusion, disorientation, paranoia, and delusions). Most patients are diagnosed with depression initially<sup>28</sup> while 15–20% of patients may present with seizures.<sup>29</sup> Some patients present with memory loss, personality changes and impaired concentration in early stages. Delusions of grandeur occur only in 10–20% of cases.<sup>29</sup> Clinical signs include pupillary abnormalities, expressionless face, intention tremors, dysarthria and hyperactive reflexes. Argyll Robertson pupils are classically described in tabes dorsalis but are commonly seen with paresis as well. Pupils, which are initially large subsequently become small, unequal, and fixed with loss of pupillary reaction to light but preservation of the accommodation reaction.

The dementia is progressive (although uncommonly, some patients may show spontaneous short periods of improvement) resulting in death in a few months to a few years. Treatment in early stages is associated with a good prognosis however a communicating hydrocephalus is known to complicate recovery in some patients.<sup>30</sup>

## Investigations

CSF findings are typical of neurosyphilis with lymphocytic pleocytosis and raised proteins. Blood and CSF VDRL/RPR are usually positive however, in some cases negative non-treponemal CSF serology may cause diagnostic difficulty in late stages. FTA-ABS test on CSF may be falsely reactive due to diffusion of serum immunoglobulins into the CSF.<sup>31</sup> Analysis of intrathecal antibody synthesis using CSF-IgG index,<sup>32</sup> CSF:serum ratio of TPHA,<sup>31</sup> CSF IgM assay<sup>33</sup> and B cells in the CSF<sup>34</sup> have been proposed but not used commonly for diagnosis in clinical practice. A PCR test on CSF for *T. pallidum* has not been studied adequately in recent years. Brain imaging using computerized tomography may show signs of cerebral atrophy suggesting a demyelinating process with decreased attenuation of cerebral white matter (frontal and parietal lobes) and enlargement of cortical sulci and ventricular dilatation.<sup>35</sup> Gummas and areas of infarction may also be seen.

## Pathology

Meningeal thickening, cerebral atrophy (frontal and parietal lobes) with demyelination and granular ependymitis are characteristic changes seen in GPI.

## Differential Diagnosis

The clinical presentation along with characteristic CSF and radiological changes forms the basis of diagnosis. The diagnosis is more difficult in elderly patients with dementia with a positive treponemal serology and inconclusive CSF picture. Alzheimer disease, degenerative dementing disease and alcoholic brain disease are part of the differential diagnosis.

### TABES DORSALIS

This condition is a rarity in the post antibiotic era having accounted for a third of the neurosyphilis cases in the first half of the twentieth century. It occurs within 5–50 years after primary infection with a peak occurring at 10–20 years. Clinical picture constitutes a classic triad of symptoms (lightning pains, sensory ataxia, bladder disturbances) and signs (pupillary abnormalities, areflexia, positive Romberg sign). Lightning pains are described as sudden paroxysms of severe localized, transient stabbing or shooting pains in the legs or any other part of the body. Paraesthesia and hyperaesthesia in the areas affected by lightning pains are common. Visceral crises involving stomach (gastric crisis—epigastric pain, nausea, and vomiting), intestines (intestinal crisis—abdominal pain, and diarrhea), rectum (rectal crisis—tenesmus) and larynx (laryngeal crisis—hoarseness, stridor and pain in larynx) are rare manifestation of lightning pains. Involvement of the dorsal spinal columns leads to loss of vibration sense and proprioception in the lower limbs. Knee and ankle reflexes are reduced or lost whilst maintaining flexor plantar response. Sensory ataxia with a broad based stamping gait is a characteristic sign. Loss of deep pain perception results in Charcot joints (painless enlargement of knee joints due to repeated trauma, Figs. 37.1 and 37.2) and trophic ulcers on soles, especially at the base of the great toe. A third of the patients develop bladder disturbances and a tenth, rectal incontinence. Eye involvement is common with Argyll Robertson pupils (described earlier) in nearly half the patients. Optic atrophy and cranial nerve involvement (particularly, the second, third, and sixth nerve) leads to blindness, strabismus, ptosis and flabbiness of facial muscles giving a characteristic tabetic facies. Involvement of the eighth nerve may lead to deafness with or without associated vestibular abnormality.

The rate of progression of the disease may vary from 6 months to 25 years from onset to development of ataxia.<sup>31</sup> Eventually the disease process may burn out even without treatment.

### Investigations

In active disease, treponemal, and non-treponemal serology is positive on peripheral blood. CSF shows classic features of lymphocytic pleocytosis, elevated protein concentration and reactive non-treponemal serology. In the pre-antibiotic era, in patients with established clinical diagnosis, even in burnt out cases, non-treponemal tests on the CSF were rarely negative.

**Fig. 37.1.** Tabes dorsalis: Charcot knee joint; the left knee joint has large effusion and valgus deformity. *Courtesy: Dr. OP Arya: Sexually Transmitted Infections and AIDS in the Tropics.* Arya OP, Hart CA, eds. Wallingford, Oxon: CAB International, 1998: Fig. 7.1.5.

**Fig. 37.2:** Tabes dorsalis: X-ray of Charcot knee joint showing destructive changes, new bone formation and loose bodies. *Courtesy: Dr. RW Galloway: Sexually Transmitted Infections and AIDS in the Tropics.* Arya OP, Hart CA, eds. Wallingford, Oxon: CAB International, 1998: Fig. 7.1.6.

### Differential Diagnosis

Adie syndrome (absent deep tendon reflexes and myotonic pupils) can be differentiated on the basis of non-miotic pupils and absence of lightning pains and ataxia. Diabetic neuropathy may be associated with sluggish pupils, ptosis, areflexia, ataxia and burning neuropathic pain. Treponemal serology is able to distinguish this condition. Subacute combined degeneration of the spinal cord can mimic tabes with ataxia and bladder

disturbances, however, absence of lightning pains and extensor plantar reflexes help in the diagnosis.

### OPTIC ATROPHY

Optic atrophy may occur along with tabes or GPI or may be an isolated finding. Uveitis may also present as a presenting feature of neurosyphilis. Syphilitic optic atrophy presents with progressive visual loss in one eye followed by the same process in the other eye.

### GUMMA

Intracerebral gumma is very rare and presents as a space occupying lesion with raised intracranial pressure. CT scan shows a low-density non-enhancing lesion and angiography shows a hypervascular blush zone around the central focal area of necrosis.<sup>36</sup>

## Neurosyphilis in HIV Infection

Atypical presentation of neurosyphilis has been a subject of many case reports. In one series of HIV positive patients, prevalence of asymptomatic neurosyphilis of at least 1% was noted on the basis of positive CSF VDRL test.<sup>37</sup> However, there have been no large studies identifying an increase in symptomatic neurosyphilis. Large treatment studies of HIV-positive and HIV-negative patients have not found any significant differences in response to treatment.<sup>3</sup>

## Cardiovascular Syphilis

Involvement of the cardiovascular system classically manifests after 15–30 years of latency with a male to female ratio of 3:1 and there is some link with heavy manual work. Aortic aneurysm, aortic insufficiency, coronary artery stenosis and myocarditis are some of the manifestations of cardiovascular syphilis. The incidence of cardiovascular syphilis has gone down significantly since the advent of penicillin and only case reports can be found in today's literature.

### PATHOLOGY

Treponemes are presumed to possibly reach the aorta by way of lymphatics during the spirochaetemia occurring in the early stages of syphilis and lodge in the aortic wall. They remain there for many years before provoking inflammation, detected in the form of perivascular lymphocytes and plasma cells. Which factors trigger this inflammation in some patients and not in others is unclear. Endarteritis is the primary pathologic process in all forms of syphilis and this is especially true with cardiovascular involvement. The vasa vasorum supplying blood to the ascending and transverse aorta are especially susceptible to this process. Endarteritis of vasa vasorum leads to patchy necrosis of the aortic media resulting in focal scarring. Damage to the elastic tissue in the aortic wall leads to aortic dilatation and aneurysm formation. However, the other layers of the aortic wall are also affected. Fibrous thickening of the adventitial layer and thickening of the intima with atherosclerotic

changes are thought to be related to treponemal infection. Due to all these changes, the aortic wall shows the classical “tree barking” appearance on autopsy. Calcification of these plaques gives an egg-shell appearance on the chest X-ray.

Aortitis is the commonest lesion in cardiovascular syphilis; however, lesions involving the coronary ostia, aortic valves and myocardium have been described.<sup>38</sup> Myocarditis and gummatous involvement of the myocardium are rare. Granulomas in the myocardium result in fibrous scars and may cause complications in the form of ventricular arrhythmias and valvular dysfunction.

## Aortic Aneurysm

Syphilitic aneurysms were the most common manifestation of tertiary syphilis in the pre-antibiotic era.<sup>31</sup> The thoracic aorta was involved in the majority with over 60% affecting the ascending aorta and 25% involving the transverse arch.<sup>31</sup> These fusiform or saccular aneurysms rarely dissected because of the thickening of the aortic wall following chronic inflammation.<sup>38</sup> The clinical course is insidious with symptoms developing only when the aneurysm impinges on surrounding structures or if it erodes through the chest wall and presents as a mass on the chest wall. Persistent chest pain and secondary symptoms, such as hoarseness of voice due to recurrent laryngeal nerve involvement, are common presentations. Chest X-ray may show egg-shell calcification described earlier. However, similar changes are seen in atherosclerosis or in old age. Angiography is useful to delineate the exact extent of the aneurysm. Surgical resection is indicated in patients with expanding aneurysm and those with symptoms.

Associated aortic regurgitation due to stretching of the aortic valve occurred in about 30% patients with cardiovascular syphilis.<sup>31</sup> The degree of insufficiency was variable. Signs of aortic regurgitation included diastolic blowing murmur along the lower left sternal border, a tambour-like second heart sound and dilated hypertrophy of the left ventricle. Differential diagnosis includes infective endocarditis, congenital valvular malformation, Marfan syndrome, ankylosing spondylitis, Reiter syndrome, traumatic cusp dehiscence and aging. Management includes valve replacement for patients with symptoms and congestive cardiac failure. Ventricular hypertrophy may not resolve after surgery.

Syphilis can also affect the coronary arteries with involvement of the ostia and the proximal few millimeters of the coronary arteries. There is an obliterative endarteritis which may lead to ischemic heart disease and sudden death.

## Late Benign Syphilis

**Synonym:** Gumma

This is a proliferative destructive granuloma which may affect the skin, soft tissue or bony structures. Cutaneous gummas can cause significant disfigurement. Involvement of visceral organs and CNS present as space occupying lesions. In the post-antibiotic era, gummas have all but disappeared and only case reports are seen in modern literature.<sup>39,40</sup>

It is thought that the gumma is a hypersensitivity response to the presence of very few *Treponemes* in late stages of the infection. Gummas are nodules with central necrosis surrounded by inflammatory lymphocytic and mononuclear infiltrate. This granuloma is encapsulated by proliferating connective tissue. Multinucleate giant cells are rarely seen. The size varies from microscopic to several centimeters. On the skin, it forms an ulcer which heals with considerable scarring.

## SKIN

Nodular and nodulo-ulcerative lesion starts as a 1–5 mm in size brownish red, deep indurated nodule (Fig. 37.3). Multiple lesions occur in an arciform pattern and are mostly seen on the face, back, and extremities. These are indolent and may remain for weeks or months. Some lesions may break down and then heal leaving an atrophic non-contractile scar. New lesions may appear in the surrounding skin and extend in a serpiginous manner.<sup>31</sup> Solitary gumma is an extension of a granuloma in the subcutaneous layers and is commonly seen on the thighs, buttocks, shoulders, forehead, and scalp.<sup>31</sup> The necrotic material may discharge through a sinus onto the skin.

## BONES

Gumma of the bones were as common as those of the skin<sup>31</sup> in the pre antibiotic era. These present with localized pain, tenderness

and swelling. X-rays show periostitis, gummatous osteitis, and sclerosing osteitis.<sup>31</sup> Gummatous involvement of the nasal bones, hard palate, and nasal septum has been described.

## SOFT TISSUE

Gumma involving the tongue, stomach, liver, and myocardium lead to specific signs and symptoms relating to that particular organ.

## Treatment

### LATE SYPHILIS

The principles of antibiotic therapy in syphilis are described in the chapter on infectious syphilis.

### LATE LATENT SYPHILIS, CARDIOVASCULAR, AND LATE BENIGN SYPHILIS

Most guidelines now recommend three doses of Benzathine penicillin 2.4 million units at weekly intervals for these patients.<sup>23,41</sup> Alternative regimens include Procaine penicillin 600,000 units IM OD for 17 days, Doxycycline 200 mg BD for 28 days, Amoxycillin 2 g PO tds plus probenecid 500 mg PO qds for 28 days.<sup>41</sup> The response to treatment in these patients is difficult to assess. In asymptomatic patients the physician has to rely on the VDRL/RPR titer which is usually serofast at a low level. Failure of therapy is usually seen with an increase in these titers.

Cardiovascular and late benign syphilis are treated in the same manner as late latent syphilis due to lack of more specific data in the modern era.

### NEUROSYPHILIS

The introduction of penicillin in the 1940s improved the outcome of neurosyphilis. A large multicenter trial involving treatment of 1086 patients with GPI identified a total penicillin dose of 6 million units as adequate for therapy.<sup>42</sup> The Centers for Disease Control and Prevention 2010 guidelines recommend intravenous aqueous penicillin G 18–24 million units daily for 10–14 days or intramuscular procaine penicillin G 2.4 million units plus probenecid 500 mg PO qds for 10–14 days.<sup>23</sup> In the UK, the duration is for 17 days with the intramuscular route as the first option compared to the intravenous route. Alternative regimens include Doxycycline 200 mg BD for 28 days, Amoxycillin 2 g PO tds plus probenecid 500 mg PO qds for 28 days, or Ceftriaxone 2 g IM (with lidocaine as diluent) or IV (with water for injections as diluent) for 10–14 days. In patients allergic to Penicillin, Ceftriaxone may be used although there is a 10% risk of cross-reaction.

Post treatment CSF examination is essential to confirm cure until CSF changes are resolved. Failure of resolution of CSF changes at the end of 1 year should warrant retreatment. If relapse has not occurred for a period of 2 years then the patient is considered as cured.

**Fig. 37.3:** Painless, ulcerated gumma on shaft of the penis. Courtesy: Dr. RR Mittal, Patiala, India.

Most guidelines recommend the same regimens of therapy for HIV infected individuals as there was no difference in the outcomes in these patients in a large study although some experts believe that the response to treatment in terms of VDRL/RPR titers is sluggish in HIV positive patients.

### Summary

Lack of complete information on late syphilis is compounded by asymptomatic nature of the disease, lack of simple and definitive diagnostic criteria and few epidemiological studies because of the dwindling number of patients with late syphilis in the post antibiotic era. Asymptomatic neurosyphilis is common—does not require extra treatment but close observation on the serology and the patient is essential. However, awareness about the late phase of the disease is important because of its possible progression to ultimately involve CNS and CVS, and this makes it imperative to consider it in the differential diagnosis when the past history is suggestive of inadequate or irregular or non-penicillin treatment of syphilis. Associated HIV disease makes the interpretation of serology difficult and also hastens the involvement of CNS. Since neurosyphilis (symptomatic or asymptomatic) can occur at any stage of syphilis, not just late syphilis, it would be best considered as a specific entity. With this specific consideration of CNS involvement, other manifestations of late syphilis in the post-antibiotic era are relatively rare, but should be considered especially in HIV-infected individuals. Diagnosis may be challenging, but therapy with penicillin is still the preferred choice.

## Introduction

Endemic treponematoses or tropical nonvenereal treponematoses include yaws, pinta, and endemic syphilis. The causative organisms belong to the order Spirochaetales, family of the Treponemataceae and genus *Treponema*. Yaws is caused by *T. pertenue*, pinta by *T. carateum*, and the causative organism of endemic syphilis is *T. endemicum*. The natural host for these organisms is man. At present, the causative agents of the different treponematoses cannot be distinguished from each other serologically, morphologically, or by other means.<sup>1</sup> The causative agents of nonvenereal and venereal treponematoses have shown minor genetic differences, but none of these variations can distinguish the subspecies.<sup>2</sup> They can be seen under the dark ground microscope as slender, silver threads coiled like a cork screw and have got a characteristic rapid spinning movement. The study of the pathology of the diseases caused by these bacteria is greatly hampered by the inability to culture any of these treponemes *in vitro*.<sup>3</sup> It has been postulated that treponematoses originated some 22,000 years ago in the Eurasian-African land mass. Poorest people of the world were affected and the diseases caused disfigurement, disability, and an economic burden.<sup>4</sup>

According to an estimate in 1996, the population at risk was about 34 million, i.e., 5% of the total world population (mainly infants, children and to a lesser extent, adolescents, and young adults). They all live in developing countries, with 21 million living in the so-called least developed countries. The regions which are affected the most are Africa and Southeast Asia, with some foci in central and South America, the Middle East, and Pacific Islands. The total number of cases estimated globally is 2.6 million and infectious cases number 460,000 of which 400,000 cases are in Africa. The number of disabled persons due to endemic treponematoses is estimated at 260,000 cases globally.<sup>5</sup>

The WHO department of control of neglected tropical diseases launched a global initiative in 2007 to eliminate yaws and other endemic treponematoses.

## HIV and Endemic Treponematoses

The immunodeficiency due to HIV might lead to reactivation of latent treponematoses. HIV-infected patients are more likely to carry a large number of treponemes and might disseminate these pathogenic treponemes more effectively than HIV-negative persons.<sup>6</sup>

## YAWS

Synonyms: Framboesia tropica (German, Dutch), pian (French), parangi, boubas (Portuguese), buba (Spanish), paru. Yaws is an ancient disease. It is a chronic, infectious, relapsing nonvenereal treponematosis.

The disease is seen in rural tropical areas where the humidity level is high and rainfall is heavy.<sup>2</sup> Other factors that favor transmission of yaws include poor socioeconomic conditions, lack of sanitation, overcrowding, and scanty clothing.<sup>7</sup> It is found in people who have little or no access to health services. Therefore, yaws is said to occur “at the end of the road”<sup>3</sup>.

## Etiology

It is caused by *T. pallidum* subspecies, *pertenue*. It is a regular, slender, spiral spirochete that is 8 µm in length and 0.2 µm in width. The number of coils vary from 8 to 16. It multiplies by transverse fission every 30 to 33 hours. *T. pertenue* is morphologically and serologically indistinguishable from *T. pallidum*, which causes venereal syphilis.<sup>8,9</sup> It does not cause congenital infections because it cannot cross the placenta. It is easily killed by drying and heat.

## Prevalence

Yaws is primarily a disease of children with a peak incidence between 6 and 10 years of age.<sup>10</sup> Some authors have described a sex difference,<sup>8</sup> i.e., it is more common in males than in females, but others feel that boys and girls are equally affected.<sup>11</sup>

It is mainly confined to the belt between the tropic of Capricorn and the tropic of Cancer. In Asia, it occurs in Indonesia, Papua

New Guinea, and the South Pacific. Cases, though in small numbers, are persistently reported from Sri Lanka and India. In India it was endemic in Andhra Pradesh, Madhya Pradesh, Maharashtra, Orissa, and Tamil Nadu prior to the mass treatment campaign in 1950.<sup>12</sup> In the Western Pacific region, three countries remain endemic—Papua New Guinea, the Solomon Islands, and Vanuata.<sup>13</sup> There are unconfirmed reports that Yaws is still present in some countries in sub-Saharan Africa and Western Pacific region. For example, in 2005 about 26,000 cases were reported in Ghana and about 18,000 cases were reported in Papua New Guinea.<sup>14</sup>

In 1952, a yaws control program was started in India with assistance from WHO and UNICEF. From 1952 to 1964, about 200,000 cases of Yaws were detected and treated in Andhra Pradesh, Madhya Pradesh, Maharashtra, and Orissa. The campaign reduced the incidence by 93%. Yaws re-emerged in 1977 in Madhya Pradesh.<sup>15</sup> A Yaws eradication program also took place in India in 1996–1997 in the Koraput district of Orissa. In 1996, 3571 cases were reported and by 2004 this had fallen to zero.

Yaws elimination is defined as Zero reporting of cases based on high-quality case searches validated by independent appraisals. Yaws eradication is defined as the absence of new cases for a continuous period of 3 years, supported by the absence of evidence of transmission through serosurveys among children aged <5 years, i.e., no seroreactivity to rapid plasma reagin or VDRL.

On September 16th 2006, yaws was eliminated from India and the government hopes to eradicate yaws by 2010.<sup>16</sup>

## Mode of Transmission

Yaws is transmitted nonvenereally by direct skin-to-skin contact. The infection spreads by close contact from an individual with an open lesion to an uninfected person with skin excoriations, scratches, bites, etc. The spirochetes cannot enter through the intact skin and breaks in continuity of the skin surface serve as portals.

Overcrowding and poor socioeconomic status favor transmission of the disease. The lack of water and soap for bathing and washing, and of shoes or clothing for children between the ages of 5 and 15 years are said to favor yaws transmission. There is no evidence to suggest indirect transmission by fomites or insects,<sup>17</sup> but theoretically it may be possible. Yaws is not transmitted sexually, but the presence of a genital lesion may cause confusion in making an accurate diagnosis.

## Clinical Features

Yaws can be classified into the early infectious stage and the late noninfectious stage. Early yaws comprises primary and secondary stages, while late yaws, the tertiary stage. In the primary stage, skin lesions are seen at the site of inoculation and in the secondary stage widespread multiple skin lesions are seen due to dissemination of treponemes. The tertiary stage is characterized by deformities.

## Early Yaws

Incubation period is same as for syphilis, i.e., 9–90 days (average 3 weeks).<sup>18</sup> The organism gains entry through minor abrasions or lacerations and multiply at the site of infection, then invades the subcutaneous lymphatics and spreads through the blood stream. The skin lesions start as one or more nontender papules that later become crusted and ulcerated (Fig. 38.1). The initial lesion is called the “mother yaws” which can persist for up to 6 months and healing occurs spontaneously leaving a large atrophic and depressed scar.<sup>19</sup> Sometimes, friable ulcerated proliferative papillomatous lesions are seen, which are very rich in treponemes.

The initial lesion is followed by multiple, small, widespread, cutaneous papules—the daughter yaws (Figs. 38.2–38.4). Constitutional symptoms like fever, malaise, and generalized lymphadenopathy may be associated with these lesions. Other cutaneous lesions seen are macules, papules, maculopapules, micropapules, plaques, and nodules. Palms and soles may show hyperkeratosis (crab yaws) (Figs. 38.5 and 38.6). Lesions in the early stage of yaws usually disappear spontaneously, sometimes leaving behind a slight pigmentary change. Painful osteoperiostitis and dactylitis can occur.<sup>20</sup> Periungual lesions of the nail fold produce deformities called pianic-onychia and even shedding of the nail.

The early stage is followed by a variable period of latency, which can be detected by serological tests.

**Fig. 38.5:** Hyperkeratotic plaques of secondary yaws on soles. *Courtesy:* Dr. DS Nagreh, Penang, Malaysia.

### Late Yaws

Late stage develops in 10% of the patients after about 5 to 10 years.<sup>18</sup> It is characterized by destructive changes. Skin, soft tissue, cartilage, and the bone (Fig. 38.7) are the sites involved. Late manifestations include gangosa (destructive ulcerative rhinopharyngitis), gummata, juxta-articular nodes, contractures, and sabre tibia (Figs. 38.8 and 38.9). Gondou is a rare feature

**Fig. 38.6:** Hyperkeratotic plaques of secondary yaws on palms. *Courtesy:* Dr. DS Nagreh, Penang, Malaysia.

**Fig. 38.7:** Periostitis of the tibia in late yaws. *Courtesy:* Dr. Nagreh, Penang, Malaysia.

characterized by exostoses of nasal and adjacent bones. Neurologic and ophthalmologic abnormalities have been reported.<sup>21,22</sup> Roman and Roman in their review article argue that there is ample evidence for CNS, cardiovascular, and congenital infections in yaws.<sup>23</sup>

Vertical transmission, as is seen in venereal syphilis, does not occur in yaws.<sup>18,24</sup>

### Histopathology

Early lesions show acanthosis and papillomatosis. There is neutrophilic exocytosis, giving rise to intraepidermal microabscesses. The dermis is infiltrated mainly by plasma cells, but other cells like neutrophils, eosinophils, lymphocytes, and histiocytes may also be present. Blood vessels are affected usually

**Fig. 38.8:** Deformity of tibia in late yaws (Sabre tibia).  
*Courtesy: Dr. DS Nagreh, Penang, Malaysia.*

**Fig. 38.9:** Anterior bowing of tibia in late yaws. *Courtesy: Dr. DS Nagreh, Penang, Malaysia.*

only mildly in yaws, in contrast to syphilis.<sup>17</sup> A large number of treponemes can be demonstrated between epidermal cells by silver impregnation or immunofluorescence.

### Laboratory Findings

Treponemes can be demonstrated by dark ground examination from skin lesions in the early stage. The serological tests include venereal disease research laboratory (VDRL) test, *Treponema*

*pallidum* hemagglutination (TPHA), and fluorescent treponema antibody (FTA-Abs) test. The rapid plasma reagin (RPR) is a slide agglutination test to detect antibodies against yaws. The test is reliable, economical, reproducible, rapid, and easy to perform even under field conditions. The specificity and sensitivity of the test is similar to that of VDRL test.

### Diagnosis

The diagnosis of yaws is based on clinical features, supplemented by dark ground examination and serological tests. A typical presentation of yaws is in an individual who lives in an endemic area and presents with one or more of the following signs: ulcer with scab, papillomas, palmar/plantar hyperkeratosis.

### Differential Diagnosis

In the tropics, a variety of skin conditions should be differentiated from yaws, which include impetigo, ecthyma, tropical ulcers, Hansen's disease, chromoblastomycosis, cutaneous leishmaniasis, scabies, and viral infections like molluscum contagiosum.

### Treatment

Penicillin is the drug of choice. Resistance to penicillin has not yet been demonstrated.<sup>25</sup> A single injection of benzathine penicillin, in the dose of 600,000 units for children below 10 years and a dose of 1.2 million units for those aged over 10 years is recommended. Tetracycline and erythromycin have been advocated in patients who are sensitive to penicillin.<sup>17</sup>

Eradication of yaws is difficult,<sup>26</sup> because:

- (i) Untreated yaws is infectious for months or years after the onset of symptoms.
- (ii) Treponemes tend to persist in the CSF and lymph nodes after treatment.
- (iii) A vaccine is not available against yaws.
- (iv) Diagnosis may be difficult in nonendemic areas.

But with active case detection, treatment, surveillance, and community awareness, yaws is amenable to eradication.

### PINTA

Synonyms: Carate (in Colombia, Venezuela), mal del pinto (in Mexico), azul (in Chile, Peru), cute and morado. It is a chronic infectious disease caused by *T. carateum*. The organism is closely related to the causative agents of yaws, venereal, and endemic syphilis.<sup>18</sup>

The disease is endemic in tropical central and South America and is considered as a disease of western hemisphere.<sup>27</sup> Since the early seventies, pinta has been extinct from the world with the exception of few scattered areas in the Brazilian rain forest.<sup>28</sup> Imported cases from these regions have been reported from the eastern hemisphere also. There is a high incidence among people who live in primitive and unhygienic conditions. The

main reservoir of the disease is young adults, who have chronic skin lesions.<sup>27</sup> Transmission occurs by direct skin or mucous membrane contact. Fomites may play a role in the transmission of pinta, but it has not been proved conclusively.<sup>29</sup> The disease is predominantly seen in children and adolescents after the age of 10 to 15 years. Both sexes are equally affected.

## Clinical Features

Pinta can clinically manifest in two stages viz., early and late. Initial primary lesions and generalized cutaneous lesions are seen in the early stage. The late stage consists of the late latent and tertiary phase. The stages frequently overlap.

After an incubation period of 7 to 21 days, an initial papular lesion develops on the exposed parts of the body, usually the legs, the dorsum of the foot, the forearm, or the back of the hands. Sometimes, an erythematous scaly plaque may be seen. Local lymphadenopathy is common. The primary lesions heal spontaneously. After several months or even years, multiple, widespread, small lesions can appear which may be hypochromic, pigmented or erythematous. These secondary lesions are called "pintides".

The late stage develops after 2 to 5 years. It is characterized by achromia, disfiguring pigmentary changes, skin atrophy, and hyperkeratosis.<sup>1</sup> Pinta affects only the skin.<sup>18</sup> Systemic symptoms are not seen in pinta; the cardiovascular and central nervous systems are not involved. Pinta is a benign disease and the prognosis is good.

## Histopathology

The early lesion is characterized by acanthosis, exocytosis of lymphocytes, and loss of melanin and liquefaction degeneration in the basal layer. The dermis shows a mixed infiltrate of plasma cells, lymphocytes, histiocytes, and neutrophils. Melanophages are seen in the upper dermis.

## Differential Diagnosis

Skin disorders associated with changes in pigmentation should be considered in the differential diagnosis. These include vitiligo, pityriasis versicolor, pityriasis alba, tuberculoid leprosy, and erythema dyschromicum perstans.

## Diagnosis

Diagnosis is mainly clinical and can be confirmed by dark-ground microscopy and serology. Treponemes can be demonstrated with silver stains in all but long-standing depigmented lesions.<sup>30</sup>

## Treatment

Benzathine penicillin is the drug of choice. A single dose of 600,000 units in patients below 10 years and 1.2 million units in those aged over 10 years is used. In penicillin sensitive patients, either tetracycline or erythromycin may be used.

## ENDEMIC SYPHILIS

Synonyms: Bejel (Arabic), firjal, dichuchwa (Zimbabwe), loath. It is a chronic infectious, nonvenereal, endemic disease caused by *T. pallidum*, subspecies *endemicum*. The organism is closely related to *T. pallidum*. In dry hot climatic zones, endemic syphilis continues to cause a problem.<sup>31</sup>

Endemic syphilis is prevalent among people who live in crowded and unhygienic conditions. It is prevalent in the rural areas of Saudi Arabia, Saharan regions in Africa, and among Bedouin tribes in the Middle East. Endemic syphilis is seen in children between 2 and 15 years of age and also in adults from infected families.<sup>18</sup> Both sexes are equally affected. The disease is transmitted nonvenereally by direct skin to skin or mouth to mouth contact. Transmission of the disease by insects has been suspected by some but has not been proven. The lesions may occur in and around the mouth as the result of using the same drinking vessels. The breastfed child can acquire this disease from a chancre on the nipple of infected mother. The spread of endemic syphilis can be controlled by improving living conditions.<sup>32</sup>

## Clinical Features

### Primary Stage

The lesions are seen in the oropharyngeal mucosa<sup>18</sup> and usually go unnoticed by patients, as they are small and transient.<sup>33</sup>

### Secondary Stage

The clinical features resemble that of secondary syphilis and are characterized by asymptomatic skin lesions, mucous patches, and lymphadenopathy. Other features are the development of condylomata lata and osteoperiostitis. The skin lesions are characterized by multiple, shallow, painless ulcers involving lips, buccal mucosa, tongue, or tonsils. Patients may also develop treponemal laryngitis leading to hoarseness of voice.

### Late Stage

This stage is characterized by the involvement of skin, bones, and cartilage. There can be destruction of the nose and palate. Clinically, patients present with gumma of the nasopharynx, larynx, skin, and bone. These lesions may progress to ulcers, which heal with depigmentation or scars with peripheral hyperpigmentation. Most frequently associated ocular findings are uveitis, choroiditis, chorioretinitis, and optic atrophy.<sup>34</sup> Neurologic and cardiovascular involvement is rare. The exact reason is not known. The causative agent, although antigenically related to *T. pallidum*, could be a mutant or a different spirochete that cannot invade the cardiovascular or nervous systems.<sup>34</sup>

## ATTENUATED ENDEMIC SYPHILIS

A clinically attenuated form of endemic syphilis has been described by Pace et al. in Saudi Arabia. In this form, the number, severity, and duration of both early and late lesions are reduced,

and the majority of seropositive persons have latent disease. The most common manifestation is persistent pain in the legs, often associated with radiological evidence of osteoperiostitis of the tibia and fibula.<sup>35</sup>

## Histopathology

The microscopic findings resemble that of venereal syphilis. There is a perivascular infiltration of plasma cells and lymphocytes. In the early stages, treponemes can be demonstrated by silver stains.

## Differential Diagnosis

Endemic syphilis must be differentiated from venereal syphilis, yaws, and pinta. The diagnosis is based on the clinical features, history, and country of origin. Other cutaneous conditions to be differentiated are psoriasis, pityriasis rosea, and lichen planus.

## Treatment

The drug of choice is benzathine penicillin and the dosage schedule is the same as described for the other treponematoses.

### Summary

- The conditions included under endemic treponematoses are yaws, pinta, and endemic syphilis.
- Yaws is caused by *T. pertenue* and is clinically characterized by crusted ulcerative lesion in the early stage and by destructive changes in the late stage.
- Pinta is a chronic infectious disease caused by *T. carateum* and clinically manifests in two stages viz. early and late.
- Endemic syphilis is caused by the subspecies of *T. pallidum*, and it is clinically characterized by three stages viz primary, secondary, and late stage.
- Benzathine penicillin is the drug of choice in endemic treponematoses.

## Introduction

Gonorrhea, caused by the obligate human pathogen *Neisseria gonorrhoeae* (the gonococcus), is the second most prevalent bacterial sexually transmitted disease (STD) globally. Gonorrhea, including its severe complications, has remained a major public health concern worldwide and causes substantial morbidity and economical cost, especially calculated as disability-adjusted life years.<sup>1,2</sup> In 2005, according to the World Health Organization (WHO) estimates there were 88 million new cases among adults worldwide. The incidences have remained high in many less-resourced settings, and also since mid- or late-1990s shown increasing trends even in many developed and more industrialized countries. Most worryingly, the bacterium has now developed resistance to nearly all antimicrobials introduced for treatment of gonorrhea, and it is a fear that gonorrhea may become untreatable in certain circumstances and especially in some settings.<sup>3–5</sup>

*N. gonorrhoeae* colonizes and infects primarily the mucosa of urogenital, anorectal, pharyngeal, and ocular regions. The clinical spectrum of gonococcal infection extends from asymptomatic mucosal colonization to frank inflammatory mucosal disease (urethritis, cervicitis, pharyngitis, proctitis, conjunctivitis). If untreated, or inappropriately treated, the urogenital infection may ascend to the upper genital tract and cause local complications such as salpingitis, pelvic inflammatory disease (PID), and epididymitis, and even serious systemic complications such as disseminated gonococcal infection (DGI), arthritis, dermatitis, endocarditis, and meningitis. Apart from causing disastrous sequelae such as ectopic pregnancy, infertility, and blindness (due to ophthalmia neonatorum), gonorrhea significantly facilitates HIV transmission through increased viral shedding from the inflamed mucosa.<sup>6</sup>

## History

Gonorrhea is one of the oldest diseases known to mankind. References suggestive of this infection were found in ancient Egyptian, Roman, Greek, Chinese, Japanese, Vedic, and Biblical (Book of Leviticus) citations. Hippocrates (ca. 460–370 BC) described the condition of “strangury” (presumably acute

gonorrhea), as a result of excessive indulgence in the pleasures of Venus. The Roman physician Celsus was aware of gonorrhea and catheterized patients with urethral stricture. Galen (ca. 130–200 AD) coined the term “gonorrhea” (gono=seed; rrhoea=flow) under the impression that the male discharge was an involuntary loss of semen (spermatorrhea). In an ancient Indian medical treatise, “dysuria” was dealt exhaustively in the chapter “Diseases of the urinary passages” by Sushruta (ca. 500 AD).<sup>7–9</sup>

Guillaume de Salicet (13th Century AD) may have been the first to describe the venereal nature by attributing the disease to the impurities retained under the male prepuce after contact with an unclean female. The term “clap” for gonorrhea first appeared in print in 1378. While the sexual transmission and contagious nature of this infection were being established in the early 15th century, controversy arose in western Europe regarding the etiology of syphilis and gonorrhea. In 1530, Paracelsus taught his disciples that gonorrhea was an early feature of syphilis. This view further gained support from the classic experiment of John Hunter who, in 1767, developed syphilis after self-inoculation of pus from the penile urethra of a patient infected with gonorrhea (who was co-infected with syphilis, but this was unknown at the time). This concept persisted for a long period despite the fact that Benjamin Bell in 1792 contended that both these diseases are separate entities. Later, Phillippe Ricord finally clarified and established the distinctive nature of both these diseases in 1831.<sup>7–9</sup>

However, full understanding was first achieved when the etiologic agent of gonorrhea, initially named “Micrococcus der Gonorrhoe,” was identified in 1879 by Albert Neisser in the stained smears of purulent urethral, vaginal, and conjunctival exudates.<sup>10</sup> Leistikow and Loeffler in 1882 grew the organism *in vitro* on culture media of blood serum and gelatin.<sup>11</sup> Bumm further established the causal relationship between the organism and the disease by producing the characteristic signs and symptoms after inoculating the male urethra with the growth obtained from culture. Demonstration of the bacteria as Gram-negative diplococci was possible with Gram staining introduced by Hans Gram in 1884.<sup>12</sup> Thayer and Blummer documented gonococcal

endocarditis and septicemia before the end of 19th century. The carbohydrate utilization test for distinguishing *Neisseria* species and oxidase test were introduced by Elser and Huntoon in 1909,<sup>13</sup> and Gordon and McLeod in 1928,<sup>14</sup> respectively. In 1964, the selective Thayer–Martin medium,<sup>15</sup> greatly facilitated the diagnosis of gonorrhea, especially in women. This was followed by many new microbiological revelations, such as the demonstration of variations in the virulence of gonococci with different colonial morphology by Kellogg and co-workers in 1963,<sup>16</sup> and elucidation of ultrastructural and immunological features of *N. gonorrhoeae*. Non-culture-based diagnostic methods were then developed during the subsequent decades. These included serological assays, such as complement fixation test, for detection of gonococcal antibodies, and antigen detection methods like direct immunofluorescence using fluorescent antibody techniques and enzyme-linked immunosorbent assays.<sup>17–21</sup> During the last two decades, genetic methods for diagnosis, such as nucleic acid hybridization (NAH) tests and nucleic acid amplification tests (NAATs), have been rapidly replacing the culture diagnostics in many developed, industrialized countries.<sup>17–26</sup> Therapy for gonorrhea has undergone several changes, replacing the old horrible therapies, such as urethral astringents, soundings, and mechanical devices with chemical therapy initially with urethral irrigation with potassium permanganate solution and silver nitrate, and later in 1936 the first antimicrobial agents, the sulfonamides,<sup>7,9,27,28</sup> followed by penicillin in 1943<sup>29</sup> were introduced for treatment. For further information on antimicrobial treatment of gonorrhea (vide infra).

## Epidemiology of Gonorrhea

Gonorrhea is the second most prevalent bacterial STD globally and has remained a major public health concern worldwide. In 1999, 62 million new cases of gonorrhea were estimated among adults (15–49 years of age) globally by the WHO.<sup>30</sup> Forty-four (71%) million of these cases were in South and South-East Asia, and Sub-Saharan Africa. In developing or less-resourced settings, the estimated number of new cases (in million) were 12.12 for males (15.09 for females) in South and South-East Asia, 8.19 for males (8.84 for females) in Sub-Saharan Africa, and 3.26 for males (4.01 for females) in Latin America and the Caribbean. In more developed industrialized settings, the number of cases were substantially lower, for instance 0.49 for males (0.63 for females) in western Europe, 0.72 for males (0.84 for females) in North America, and 1.59 for males (1.68 for females) in East Asia and the Pacific. In 2005, 88 million new cases among adults worldwide were estimated by the WHO, the WHO South-East Asia region (23 million cases) and the WHO Western Pacific region (27 million cases) accounted for 57% of the global burden of new infections (Fig. 39.1) (WHO. *Prevalence and Incidence In 2005 Of Sexually Transmitted Infections: Methods And Results*. Geneva: World Health Organization 2011. In Press). The incidences have remained high in many developing less-resourced settings, and also since mid- or late-1990s shown

**Fig. 39.1:** Estimated new cases (million) of gonorrhea by WHO region among adults between the ages of 15 and 49 years, 2005. *Source:* WHO. *Prevalence and incidence in 2005 of sexually transmitted infections: methods and results*. Geneva. World Health Organization, 2011. In Press.

increasing trends, after approximately two to three decades of decline, in many developed, more industrialized countries such as in several Western European countries. Furthermore, due to the sub-optimal diagnostics, and incomplete case reporting and epidemiological surveillance in many countries, the reported incidences are also underestimated in many countries worldwide. The mentioned decline in gonorrhea rates during the 1970s and 1980s in, for example, many Western European countries and in the USA was probably due to multifaceted reasons, widespread education resulting in safer and more protected sexual behavior, improved diagnostic methods, appropriate antibiotic treatment, more effective contact tracing and, information about and fear of HIV and acquired immunodeficiency syndrome (AIDS) from the mid-1980s and onward.

The risk factors for gonorrhea widely differ in divergent societies but may include poverty, unemployment, migration of populations, illiteracy, early onset of sexual activity, being unmarried, being man who have sex with man (MSM), previous gonorrhea or other STD, concomitant other STD, young age, many new or multiple partners, inconsistent condom use, drug use and commercial sex.

## Biology of *Neisseria gonorrhoeae*

*N. gonorrhoeae* belongs to the family Neisseriaceae that includes five genera, i.e., *Neisseria*, *Kingella*, *Eikenella*, *Simonsiella*, and *Alysiella*.<sup>17</sup> The genus *Neisseria* contains two human pathogenic species, *N. gonorrhoeae* and *N. meningitidis*, and approximately 30 apathogenic commensal species that inhabit, e.g., the mouth and upper respiratory tract, but also rarely can be found in the urogenital tract. *N. gonorrhoeae* is a Gram-negative, aerobic, capnophilic, non-flagellated, non-sporulating, and oxidase and catalase producing coccus. In microscopy, *N. gonorrhoeae* (1.25–

1.6 × 0.7–0.8 μm in size) is typically observed in pairs (diplococci) with adjacent sides concave, i.e., appears in a characteristic kidney or coffee bean morphology. *N. gonorrhoeae* is fastidious and requires complex nutritionally enriched culture medium for *in vitro* growth. The bacterium can only utilize glucose, lactate or pyruvate as carbon source that is used in the species-verifying carbohydrate utilization test in which *N. gonorrhoeae* only degrades glucose (not maltose, fructose, sucrose or lactose). Human is the only natural host for *N. gonorrhoeae*, which survives poorly outside the human body due to its sensitivity to extreme temperatures, desiccation, oxidation and toxic substances. Ideal *in vitro* growth is obtained at 35–37°C in a 4–6% CO<sub>2</sub> atmosphere at a pH of about 6.5–7.5.<sup>9,17,18,20,26</sup>

Different *N. gonorrhoeae* strains display a high heterogeneity, genetically and phenotypically. This is due to its extensive genetic exchange within the species and with related species, using transformation (natural competence during entire life cycle) and conjugation (plasmid DNA), that results in recombination of partial or complete genes, high mutational frequency, and many phase-variable genes. In fact, *N. gonorrhoeae* has a non-clonal, sexual, and panmictic population structure. This high variability of *N. gonorrhoeae* is valuable for evasion or adaptation to the immune response of the host and for development and spread of antibiotic resistance mechanisms. These properties make the bacteria effective in persisting without severely damaging the host, i.e., in producing mildly symptomatic or asymptomatic infection.<sup>26</sup>

## Molecular Structures of *N. gonorrhoeae*

### GENOME OF *N. GONORRHOEA*

#### Chromosome

Already in 2000, the first genome of a gonococcal strain (FA1090) was assembled as one contig (2,153,922 base pairs (bp); GenBank accession no. AE004969). Recently, additional 16 genomes were finished and published online (n=14; [http://www.broadinstitute.org/annotation/genome/neisseria\\_gonorrhoeae/GenomeDescriptions.html](http://www.broadinstitute.org/annotation/genome/neisseria_gonorrhoeae/GenomeDescriptions.html)) or in scientific papers (n=2).<sup>31,32</sup> All these genomes had a size of 2.1–2.2 Mb, 52–53% GC content, and encoded 2100–2300 genes.

#### Plasmids

**Cryptic plasmid:** In 1973, a cryptic plasmid in *N. gonorrhoeae* was first reported. The plasmid is present in the majority of strains, but not in all auxotypes of *N. gonorrhoeae*.<sup>33</sup>

**β-lactamase encoding plasmids:** In 1976, two different β-lactamase producing plasmids in *N. gonorrhoeae* strains from South-East Asia and Sub-Saharan West Africa were reported from the USA and the United Kingdom, respectively.<sup>34,35</sup> The origin of these plasmids might be a *Haemophilus* species. The β-lactamase (penicillinase) was of TEM-1 type, which causes high-level penicillin resistance by hydrolyzing the cyclic amide

bond in the β-lactam ring. Penicillinase producing *N. gonorrhoeae* (PPNG) strains and these “Asian” and “African” plasmids are now globally widespread.<sup>5,26</sup> However, other types of β-lactamase encoding plasmids have also been described, e.g., the Rio/Toronto, Nimes, New Zealand, and recently Johannesburg plasmid. The Asian plasmid is probably the ancestral plasmid from which all these plasmids have been derived by means of insertions and/or deletions (indels).<sup>36,37</sup>

**Conjugative plasmids:** The first *N. gonorrhoeae* conjugative plasmid was identified in 1974.<sup>33</sup> This plasmid can transfer β-lactamase encoding plasmids between *N. gonorrhoeae* strains, and also to other bacteria like *N. meningitidis*. A derivative of the conjugative plasmid, a *tet*(M)-carrying conjugative plasmid, was described in 1985.<sup>38</sup> This plasmid was assigned the American *tet*(M) plasmid, expressed the TetM determinant initially identified in *Streptococcus*, and mediated high-level resistance to tetracycline. In 1991, the homologous Dutch *tet*(M) plasmid was described,<sup>39</sup> and a Uruguayan *tet*(M) plasmid has also been proposed.<sup>40</sup> Nowadays, tetracycline-resistant *N. gonorrhoeae* (TRNG) with the *tet*(M)-carrying self-mobilizing plasmids are widespread.<sup>5,26</sup>

### Outer Membrane Structures of *N. gonorrhoeae*

Outer membrane structures of *N. gonorrhoeae*, e.g., pilus, lipooligosaccharides (LOS), PorB, and Opa proteins are involved in the adhesion to the epithelial surface of the human host, invasion through the epithelial cell layer, and interactions with leukocytes. These structures have been extensively studied to elucidate the pathogenicity of gonorrhea, virulence of different strains, targets for diagnostics or potential vaccine candidates, and for phenotypic and genotypic characterization of *N. gonorrhoeae*.<sup>26</sup>

### Cell Wall and Outer Membrane

The cell wall consists of a Gram-negative bilayered outer membrane (phospholipids, LOS, and proteins) overlying a relatively thin peptidoglycan layer (in the periplasm) containing N-acetyl glucosamine, N-acetyl muramic acid, glutamic acid, diaminopimelic acid, and alanine. The bilayered inner membrane (cytoplasmic membrane) envelops the colloidal system of cytoplasm composed of organic and inorganic solutes dispersed in a viscous solution.<sup>9,20</sup> A schematic drawing of the cell wall is seen in Fig. 39.2.

### Lipooligosaccharide

The LOS consists of a lipid A moiety, which confines the endotoxic activity eliciting a host immune response, and a core oligosaccharide (composed of keto-deoxyoctanoic (KDO) acid and glucose, heptose, galactose, glucosamine, and/or galactosamine). The LOS is involved in adhesion, invasion, and toxicity of host epithelial cells. LOS is a target for bactericidal and chemotactic antibodies, however, sialylation of the LOS increases the antigenic variation and affects the invasion of epithelial cells, inhibits bactericidal activities of antibodies against PorB, LOS,

**Fig. 39.2:** Schematic drawing of the cell wall in *Neisseria gonorrhoeae* showing molecular structures such as pilus, lipooligosaccharide (LOS), opacity (Opa) protein, reduction modifiable protein (Rmp), the porin PorB, the outer membrane protein A (OmpA), penicillin binding protein 1 (PBP1) and PBP2. For example, the MtrCDE efflux pump and the IgA1 proteases, which are described in the text, are not shown. The figure was initially prepared by Dr. Susanne Jacobsson (Örebro University Hospital, Sweden) and then modified by the author (Unemo M).

and Opa proteins, phagocytosis of neutrophils, and complement activation by factor H binding, and may consequently result in serum resistance.<sup>9,41–43</sup> Intrastrain as well as interstrain variations of the antigenicity, lengths, and/or presence of any of the three oligosaccharide side chains, the number of LOS components expressed, and/or the relative concentration of the various components are frequent.<sup>9,41–43</sup>

## Pili

Pili are hair-like appendages, composed of thousands of pilin (PilE) protein sub-units in association with some other pilus-associated proteins that are extending several micrometers outside the bacterial cell. Pili are associated with the initial adhesion to human epithelial cells, they promote virulence by preventing neutrophilic phagocytosis, and mature pili or at least the major subunit of the pilus fibre, PilE, and PilC are essential for a high-level transformation of exogenous DNA.<sup>9,44</sup> High-frequency antigenic variation of pili results predominantly from recombinational events between several variable chromosomal silent *pilS* loci, in which the genes lack the 5'-end and promoter region of a functional PilE encoding gene, and usually one expressed *pilE* locus, encoding PilE. Hypervariable sequences of *pilS* may also be subject to horizontal exchange between the different *pilS* genes and to interstrain recombination.<sup>9,45</sup> Phase variation by on/off switch in the expression of PilC, a pilus-associated protein that is involved in biogenesis and adherence functions of the pilus, is also frequent.<sup>9,44,45</sup>

## Porin Protein

PorB (previously named major or principal outer membrane protein (MOMP/POMP), Protein I (P.I), or Por) is universally

present in the outer membrane, physically proximate to the LOS and reduction modifiable protein (Rmp), as trimeric pore-forming transmembrane proteins (porins) that allow small hydrophilic solutes and anions to diffuse through the outer membrane.<sup>9,46,47</sup> PorB is a target for bactericidal opsonic antibodies, however, it also comprises the ability to translocate into the cell membrane of eukaryotic cells, induces apoptosis of target cells, is involved in Opa-mediated and also Opa-independent invasion of epithelial cells, mediates evasion of complement-dependent bactericidal activities, and interferes with the activation, degranulation, and phagocytosis of neutrophils.<sup>9,46–50</sup> Any individual gonococcal strain expresses only one of two different groups of the proteins PorB1a and PorB1b.

## Opacity Protein

The outer membrane opacity (Opa) proteins, previously named heat-modifiable proteins or Protein II (P.II), contribute to colony opacity when cultured on specific media.<sup>51</sup> The Opa proteins facilitate intimate attachment between gonococci within culture colonies, and attachment to and invasion of epithelial cells and neutrophils of the host.<sup>9,51–54</sup> Up to 12 genetic loci encoding the Opa proteins exist in each strain, which may express none, one or several (usually 4–5) of these 12 antigenically different proteins.<sup>9,51–53</sup> Antigenic variation occurs because of variable expression of the different *Opa* genes.<sup>9,52,54</sup> Intragenic recombinations also occur in the *Opa* genes within and between lineages, and mutations further increase the heterogeneity of the *Opa* genes, and result in a higher level of antigenic variation and evasion of the host immune system.<sup>9,52,54</sup>

## Other Proteins

Rmp (previously named P.III) is a conserved and immunogenic protein, which is closely associated with the PorB porin in the outer membrane. Rmp is constitutively expressed, and non-bactericidal antibodies that recognize this protein, or homologous proteins in other *Neisseria* species, may block the bactericidal complement-dependent activity of antibodies that recognize, e.g., PorB and LOS.<sup>9,20,55</sup> Immunoglobulin A1 (IgA1) proteases, which are extracellularly secreted by pathogenic *Neisseria*, have been proposed to promote mucosal colonization due to their degradation of IgA1 antibodies. However, more recent studies have suggested that the IgA1 proteases are not a significant factor in the pathogenesis in the lower urogenital tract of the female.<sup>56</sup> Nevertheless, the IgA1 proteases may be important for intracellular survival in epithelial cells through alterations of the lysosomes.<sup>57</sup>

## Characterization of *N. gonorrhoeae* for Epidemiological Purposes

The epidemiologic characteristics of gonorrhea and of the heterogeneous *N. gonorrhoeae* strains fluctuate over time in both local and global perspectives. Thus, discriminative, reproducible,

and precise characterization of the bacteria can result in increased knowledge about strain populations in the community, about temporal and geographic changes, as well as concerning the emergence and transmission of certain (e.g., those that are more virulent or antibiotic resistant) strains. This information can be very valuable, together with epidemiological information, for identifying core groups and risk behaviors, test-of-cure and contact tracing, recommending effective antimicrobial treatment, and for the development of improved control measures and targeted interventions.<sup>58</sup>

## PHENOTYPIC CHARACTERIZATION

### Auxotyping

The first method for characterization of *N. gonorrhoeae*, auxotyping, was described in 1973.<sup>59,60</sup> Auxotyping divides strains into auxotypes based on their divergent nutritional requirements for amino acids, purines, pyrimidines, and vitamins. This method was earlier helpful in assessing the potential virulence, invasiveness,<sup>61–63</sup> antimicrobial susceptibility, and genetic constitution of various gonococcal strains.

### PorB-based Serological Characterization

Serogroup (WI [PorB1a protein] or WII/III [PorB1b protein]) determination and the sub-dividing serovar determination, e.g., by using co-agglutination technique, with monoclonal antibodies (MAbs) are based on antigenic diversities of the outer membrane protein PorB. This has been the most widely used approach for serological characterization of *N. gonorrhoeae* and during recent decades mainly internationally more widely used Genetic Systems panel,<sup>64</sup> and the Pharmacia panel<sup>65</sup> of MAbs have been used.

### Antimicrobial Susceptibility Testing

Historically, the antibiograms of *N. gonorrhoeae* strains were used to determine relationships between bacterial isolates. However, the antibiograms comprise a low discriminatory ability between isolates and are not stable over time. Antibiograms should not be used as a reliable epidemiological characterization method. Nevertheless, antibiograms may supplement other characterization methods. The antibiograms also generate valuable clinical information and are essential for monitoring of the changing patterns of antibiotic susceptibility, thereby contributing to early warnings of emergence of resistance to different antibiotics.<sup>58</sup>

Agar dilution method is the gold standard method for susceptibility testing or determination of the minimum inhibitory concentration (MIC) of different antimicrobials. However, this method can be labor intensive and less suited for routine susceptibility testing, especially if a low number of strains are tested, and therefore a standardized and quality assured Etest method is commonly used (Fig. 39.3). Some disk diffusion methods are also in use, however, these require pronounced standardization and appropriate quality controls to attain a high level of reproducibility and reflection of the true MIC of

**Fig. 39.3:** Antimicrobial susceptibility testing of *Neisseria gonorrhoeae* using the Etest method.

the different antimicrobials.  $\beta$ -lactamase production is often analyzed by a chromogenic cephalosporin test, using nitrocefin disks or solution.<sup>26</sup>

Unfortunately, the phenotypic epidemiological characterization methods suffer from several disadvantages, e.g., sub-optimal discriminatory ability, limited access to MAbs of adequate quality and directed against all newly evolved antigenic epitopes, problems concerning reproducibility, and subjectiveness.<sup>58</sup> All conclusions regarding strain type and distribution acquired using phenotypic characterization methods should be interpreted with caution.<sup>58</sup>

## GENOTYPIC CHARACTERIZATION

Over the past two decades, to overcome the limitations of the phenotypic characterization methods many more powerful molecular (mostly DNA-based) characterization methods have been developed. These methods can be broadly divided into two groups—those methods involving analysis of DNA banding patterns by gel electrophoresis (gel-based DNA-based typing method) and those based on DNA sequence analysis (DNA sequence-based typing methods). Gel-based DNA-based typing methods include plasmid content analysis or restriction fragment length polymorphism (RFLP) determination using pulsed-field gel electrophoresis (PFGE), ribotyping, and Opa-typing. DNA sequence-based typing methods include full- or extended-length *porB* sequence analysis, *N. gonorrhoeae* multi-antigen sequence typing (NG-MAST), and multi-locus sequence typing (MLST). A recent review in detail describe all these methods, their usefulness, and provides recommendations when each method could be beneficially used.<sup>58</sup>

In general, appropriate, validated, and quality assured genotypic methods based on DNA sequencing have been internationally recommended for use, if available and affordable, and the selection of the appropriate genotypic method should be guided by its performance characteristics and whether short-term epidemiology (microepidemiology) or long-term and/or global epidemiology (macroepidemiology) matters are being investigated. Accordingly,

the questions asked in relation to the specific situation should guide the use of the most effective typing method or methods and, the typing results should be interpreted with the actual scientific, clinical, epidemiologic, or other information. Currently, for microepidemiological questions, the best methods for fast, objective, portable, highly discriminatory, reproducible, typeable, and high-throughput characterization are NG-MAST (examines the variable internal fragments of *porB* and *tbpB*), or full- or extended-length *porB* gene sequencing. However, PFGE (potentially indexing the whole genome) and Opa typing (examines the 12 Opa genes) can be valuable in specific situations, i.e., extreme microepidemiology, despite their limitations. For macroepidemiological studies and phylogenetic studies, DNA sequencing of chromosomal housekeeping genes, such as MLST, can provide a more nuanced understanding; however, the choice of appropriate and informative housekeeping genes are imperative.<sup>58</sup>

## Pathogenesis of Gonorrhea

*N. gonorrhoeae* has a predilection for non-ciliated columnar and cuboidal epithelium in adults. After the bacterium enters into the urogenital tract of the host, it adheres to the mucosal cells initially by means of pili, and then the outer membrane proteins, in particular, Opa proteins, but also iC3b, LOS, OmpA, and PorB facilitate an intimate adhesion and subsequent internalization and transcytosis. Simultaneously with the attachment, gonococcal LOS (endotoxin) also inhibits ciliary motility and damages proximate ciliated cells.

Following adherence, the organism is enfolded by pseudopods and pinocytosed by the epithelial cells where it divides and multiplies. Intracellularly, the organisms are resistant to immune attack. Gonococcal invasion is mediated also by the outer membrane PorB protein. After adherence, the PorB protein is translocated from the bacterial cell membrane to the epithelial cell membrane. The PorB1a protein is more effectively transferred into the epithelial membranes compared to PorB1b. Epithelial cell damage is mediated by release of certain enzymes like phospholipase and peptidase or due to LOS and peptidoglycan (both comprising endotoxic activity).<sup>9,20</sup>

The organisms are then exocytosed into the sub-mucosal region where they elicit a severe neutrophilic response and form microabscesses followed by exudation of purulent material into the lumen of the infected organ. The LOS antigens elicit the C5a-dependent chemotactic response.<sup>9,20,66</sup>

When the attack is prolonged, there is proliferation of the epithelium with subsequent formation of a stratified epithelial layer. Ultimately, keratinization and fibrosis occur leading to scarring and stricture formation. The infiltrate at this stage consists of lymphocytes and plasma cells besides polymorphonuclear leukocytes (PMNL) and eosinophils.<sup>9</sup>

## Disease Transmission

*N. gonorrhoeae* is an obligate pathogen and infected human is the only natural reservoir of the bacterium. *N. gonorrhoeae*

is primarily transmitted by direct human-to-human contact between the mucosal membranes of the urogenital tract, anal canal, or the oropharynx, mainly during sexual activities (vaginal or anal intercourse, or oral sex [fellatio or cunnilingus]). The efficiency of transmission of gonorrhea depends on anatomic sites infected, anatomic site exposed, and the number of exposures. The transmission efficiency (transmission through one exposure [vaginal intercourse]) has been estimated to be 20% from an infected woman to an uninfected man; however, following four exposures the transmission efficiency increases to 60–80%. The transmission efficiency from an infected man to an uninfected woman has been estimated to be as high as 50–90%.<sup>67,68</sup> In a study from 2000, the probable source of anorectal gonorrhea in MSM was determined; urethra and pharynx were the site of infection in 72% and 20%, respectively, of the cases.<sup>69</sup> A prospective cohort study examining brothel-based female commercial sex workers who practiced oral sex revealed that 5.2% of the sex workers contracted pharyngeal gonorrhea.<sup>70</sup> Transmission of the disease from pharynx to urethra can occur.<sup>71</sup> Neonates can be infected during passage through the birth canal if the mother has urogenital gonorrhea. This non-sexual transmission mainly causes ocular infections in the neonates (ophthalmia neonatorum).

Transmission by fomites or through non-sexual routes is extremely rare and there is no convincing evidence that any transmission occurs by toilet seats or droplet infection.

Gonorrhea is initiated as a pyogenic infection of the urethra in males and the endocervix in females. The incubation period varies from 1 to 14 days, with an average of 2–7 days. However, urogenital gonorrhea is asymptomatic in approximately 50–80% of women and 2–10% of men (varies by population studied, diagnostic methods used, duration of infection, etc.).<sup>9,21,72,73</sup> Anorectal and oropharyngeal gonorrhea, which can be common among MSM but also increasing in prevalence in heterosexual individuals in several countries, are very frequently asymptomatic. All these asymptomatic individuals form a reservoir of infection, which can effectively be further transmitted as well as progress into severe complications and sequelae.

## Clinical Manifestations of Symptomatic Gonorrhea

The clinical spectrum of gonococcal infection are listed in Table 39.1.

### ACUTE UROGENITAL GONORRHEA IN MEN

This clinical manifestation mainly presents as *acute anterior urethritis*, which is characterized by symptoms of dysuria and voluminous urethral discharge. The patient can have a profuse, yellow to yellowish-green purulent discharge, edematous lips of the external urinary meatus and associated perimeatal erythema (Fig. 39.4). Tender inguinal lymphadenopathy may be present. About one-quarter of the patients develop only a scant or minimally purulent exudate indistinguishable from non-gonococcal urethritis and a minority may never develop

overt signs and symptoms of urethritis. If appropriate treatment is not initiated, *posterior urethritis* may ensue in approximately 10–14 days, which presents as frequency of micturition, urgency, occasional strangury, and rarely tenesmus. Erection may be painful. In severe cases, few drops of blood at the end of micturition may be noticed.<sup>21</sup>

Acute gonococcal infection may involve the glands of Tyson, periurethral glands of Littre and paraurethral glands. *Acute tysonitis* presents as a pea-sized uni- or bilateral, erythematous, and tender swelling on either side of the frenulum. It may rupture spontaneously discharging pus which contains gonococci. *Periurethral gland involvement* presents as small follicular abscesses in the urethral wall. These coalesce to form a large abscess that infiltrates the corpus spongiosum leading to painful erection or ventral angulation of the penis. It may rupture to form a discharging sinus on the penile skin. The majority of these abscesses are localized along the bulbar part of the urethra and fossa navicularis. *Inflammation of the paraurethral glands* is observed as erythema, edema, and pus discharge from the paraurethral ducts present on either side of the external meatus. *Gonococcal balanitis* may rarely occur in uncircumcised patients. Pustular lesions over the penile skin associated with shallow ulceration around the frenulum may also develop.

Acute cowperitis, prostatitis, seminal vesiculitis, and epididymitis are additional acute complications in males especially when the posterior urethra is affected. In *acute cowperitis*, the patient experiences pain and heaviness in the perineum. It may be associated with increased frequency of micturition or pain on defecation. Acute retention of urine due to reactive spasm of the posterior urethra may occur. Abscess formation can occur which is palpated on per rectum examination as a unilateral, tender mass between the layers of the triangular ligament in the perineum. In *acute prostatitis*, there is suprapubic discomfort, pain on defecation or even retention of urine. Rectal examination reveals an enlarged, edematous tender and fluctuant prostate. Formation of a prostatic abscess is heralded by high-grade fever associated with constitutional features, increased frequency or acute retention of urine, pain on defecation or tenesmus, and terminal dysuria. It is palpable as a large, tender, and tense swelling bulging into the rectum. It may rupture into the urethra resulting in profuse urethral discharge, or into the rectum causing acute proctitis. It may also lead to sinus formation in the perineum or adjoining skin. *Seminal vesiculitis* is associated with painful penile erection and ejaculation, or occasionally blood-stained semen. On per rectal examination, inflamed seminal vesicles can be palpated as elongated, swollen, sausage-shaped masses. *Gonococcal epididymitis* is rare. Infection occurs either by lymphatic spread or as a result of retrograde passage of urine along the lumen of the vas deferens to the epididymis secondary to excessive pressure during urethrovesicular irrigation, vigorous prostatic massage, urethral instrumentation, or excessive sexual indulgence. The condition is usually unilateral and the lower pole of the epididymis is initially affected. At the onset, symptoms of urethritis often cease temporarily and on examination the epididymis is swollen,

infiltrated, and exquisitely tender in association with redness and swelling of the overlying skin. Hydrocele formation may occur.<sup>21</sup>

### COMPLICATED UROGENITAL GONORRHEA IN MEN

Even in absence of appropriate treatment, spontaneous resolution occurs in the majority of urogenital cases within 4–6 weeks, with 95% of cases becoming asymptomatic within approximately 6 months. In rare instances, if the patient goes untreated or is inappropriately treated, serious sequelae may ensue. The patient may develop urethral strictures (Fig. 39.5), fistulae leading to “watering-can perineum” (Fig. 39.6), chronic littritis, cowperitis, prostatitis, seminal vesiculitis or epididymitis. Penile lymphangitis associated with regional lymphadenitis and penile edema (bull-headed clap) are other complications.

*Urethral strictures* may be annular involving a localized area of the urethra or “diaphragmatic” affecting a larger segment. The bulb of the urethra is the most frequently affected region, although any part may be involved. The urethral mucosa appears pale and firm in the area of the stricture. It can be detected on urethroscopy or by urethrogram. *Chronic littritis* presents as small firm nodules in the urethral wall. In *chronic cowperitis*, the patient complains of pain or heaviness in the perineum. An organized, tender abscess can be palpated pointing towards the perineum. *Chronic prostatitis* is recognized as continued symptoms as observed for acute over long time period. *Seminal vesiculitis* is characterized by “morning gleet” or frequent nocturnal emissions. Per rectal examination reveals a fusiform, indurated swelling on either side of the prostate. *Chronic epididymitis* presents as a fibrous nodule or nodular thickening, palpable at the root of scrotum.

**Fig. 39.5:** Urethrogram showing urethral stricture in male patient with complicated gonorrhea.

**Fig. 39.6:** “Watering-can perineum”-complicated gonorrhea (male) with streaks of urine from fistulae during micturition.

Sub-acute exacerbations may occur giving rise to pain, swelling, and tenderness. Recurrent episodes lead to blockade of the lumen resulting in stricture formation and sterility.

### ACUTE UROGENITAL GONORRHEA IN WOMEN

Uncomplicated gonorrhea in women remains asymptomatic in more than 50% of the cases and, accordingly, these women may act as an important reservoir of infection. These patients are diagnosed on the basis of screening or because their sexual partners are diagnosed with gonorrhea (contact tracing). The primary site of infection in females is the endocervical canal. The bacterium initially colonizes the lower urogenital tract such as the urethra, Bartholin and Skene glands and ascends to involve the cervix, and possibly subsequently the upper genital tract, i.e., the uterus, fallopian tubes, and the pelvis, whereas the vulva, vagina, and bladder are relatively spared. If symptomatic, acute gonococcal infection in females most frequently presents as *endocervicitis*, which is characterized by purulent vaginal discharge, dysuria, and sometimes post-coital bleeding. On speculum examination, copious pus emanating from the external cervical os can be visualized. There is severe erythema and edema of the cervix, and associated mucosal bleeding induced by swabbing the endocervix. Cervical erosions may also be present. Urethral discharge often goes unnoticed in females. Purulent discharge may be expressed by massaging the urethra from above downwards through the anterior vaginal wall. Endocervicitis may result in blockade of the cervical glands and formation of retention cysts or Nabothian follicles that protrude into the vaginal portion of cervix.<sup>21,74</sup>

*Acute skenitis* presents as tenderness in the terminal part of urethra and a bead of pus can be expressed at the ductal orifice (Fig. 39.7). It may commonly lead to abscess formation, which is felt as a tender, indurated mass on either side of the terminal urethra. In *acute bartholinitis*, the patient complains of pain and difficulty on walking and heaviness of the genitalia. Bartholin

**Fig. 39.7:** Skene gland abscess opening in distal urethra.

abscess is palpable as a tender, fluctuant mass at the junction of the upper two-thirds and lower third of the labia majora. A bead of pus can be expressed from the ductal opening on the inner surface of labia minora at the junction of lower and middle third. Acute *gonococcal vulvitis* is rare and may present as edema, erythema, and tenderness of the labia. Pus emanating from between the labia minora causes intertrigo and excoriation of the groins and thighs. *Gonococcal cystitis* and *trigonitis* may be occurring but are extremely rare.

### COMPLICATED UROGENITAL GONORRHEA IN WOMEN

PID is the most common local complication, which according to early studies can occur in 10–20% of untreated cases with acute urogenital gonorrhea.<sup>75</sup> The incidence of gonococcal PID is highest during the early proliferative phase of the menstrual cycle. This is at least partly due to changes in both the function of complement system and antibacterial activity of serum secondary to changes in sex hormone levels.<sup>76</sup> Symptomatic PID is less prevalent among women who use oral contraceptives.<sup>77</sup> Acute salpingitis usually occurs by retrograde intraluminal spread of infection along the surface of the endometrium. There is exudation of pus into the lumen of fallopian tubes with associated inflammation which can cause blockade of the fimbriated ends, resulting in pyosalpinx. The tubes may become adherent to the ovary, the central area of which breaks down to form a tubo-ovarian abscess. The infection can spread to the pouch of Douglas or pelvic peritoneum resulting in pelvic abscess or peritonitis. Acute salpingitis presents as acute lower abdominal pain accompanied by fever and constitutional features, menstrual irregularities or dyspareunia.<sup>21,75–77</sup>

On examination, localized tenderness in the iliac fossae associated with lower abdominal rigidity and guarding can be elicited. Bimanual pelvic examination reveals pain in the lateral fornices and on moving the cervix. A tender, fluctuant mass suggestive of pyosalpinx or tuboovarian abscess can also be palpated through the lateral fornices. Pelvic abscess presents as a tender, boggy mass in the pouch of Douglas and pus containing gonococci can be obtained by culdocentesis. Pelvic peritonitis is diagnosed by the presence of constitutional features with lower abdominal

rigidity and rebound tenderness. It is usually associated with fever and constitutional symptoms, raised erythrocyte sedimentation rate (ESR), leukocytosis, and elevated levels of C-reactive protein. PID is a serious health problem resulting in an increased risk of tubal infertility, ectopic pregnancy or chronic pelvic pain.<sup>21,75–78</sup>

Organization of pus in the pelvic peritoneum leads to adhesions between pelvic organs and the intestines, referred to as frozen pelvis. Fibrous bands can constrict the intestines causing intestinal obstruction. These bands pull the cervix to one side and the uterus may be bound down in a retroverted position.

Chronic urethritis, skenitis, bartholinitis, and proctitis are other possible complications in women.

### ANORECTAL GONORRHEA

Gonococcal proctitis in males usually results from anal coitus in passive MSM.<sup>79</sup> However, it may also be acquired via the oropharynx following orogenital sexual contact.<sup>80</sup> In women, the rectal mucosa is infected in up to 35–50% of cases with gonococcal cervicitis consequent upon perineal contamination with infected cervical secretions. According to studies in the 1980s, it is the only site of infection in 5% of women with gonorrhea.<sup>21,81,82</sup> However, changed sexual behavior, including more frequent anal intercourse also among heterosexual individuals, during the recent decades may have increased this figure, especially in some settings.

The signs and symptoms vary from minimal anal pruritus, painless mucopurulent discharge, and scant rectal bleeding to severe rectal pain and tenesmus associated with blood and mucus in the stool. Proctoscopy reveals red, edematous, and friable rectal mucosa that bleeds easily. Pus is usually evident on the mucosal surface and erosions may be present. Perianal and ischiorectal abscesses or anal fissures may develop.<sup>21</sup>

### PHARYNGEAL GONORRHEA

Oropharyngeal infection has been reported in about 3–7% of heterosexual men with gonorrhea, 10–25% of infected MSM and 10–20% of infected women.<sup>21,79,81</sup> However, also for this manifestation changed sexual behavior, including more frequent oral sex, during the last decades may have increased these figures, especially in some settings. Oropharynx is the sole site of infection in approximately 5% of cases. The infection is transmitted by orogenital contact and is more efficiently acquired by fellatio than by cunnilingus.<sup>80</sup> The symptoms are usually absent or mild in 90% of cases, although in a few instances, acute pharyngitis or tonsillitis may occur associated with fever and cervical lymphadenopathy. Pharyngeal gonorrhea may be a risk factor for developing DGI.<sup>81</sup>

### GONOCOCCAL CONJUNCTIVITIS

Gonococcal conjunctivitis is a rare entity in adults and most commonly seen in patients with concomitant urogenital and anorectal gonorrhea as a consequence of direct contamination by fingers or towels. The condition may vary from asymptomatic or mild infection to severe forms resulting in corneal ulceration and panophthalmitis.<sup>82</sup>

## DISSEMINATED GONOCOCCAL INFECTION

DGI results from hematogenous spread of infection to sites remote from the focus of infection. Sialylation of the LOS results in resistance to the bactericidal action of serum, an attribute necessary for dissemination into the blood to occur. DGI is also referred to as the 'acute arthritis-dermatitis syndrome'. The incidence of DGI has been shown in studies from the 1970s and 1980s to vary from 0.2% to 3% in patients with untreated mucosal gonorrhea,<sup>83–86</sup> however, these figures also vary, temporally and geographically, due to the gonococcal strain population circulating in different settings. This is because some gonococcal strains (which vary in prevalence, temporally and geographically), such as the AHU- auxotypes, have been shown to be more virulent and/or invasive, and accordingly more strongly associated with DGI.<sup>61,63</sup> Although the hematogenous spread of infection from a primary focus is implicated in the pathogenesis of DGI, the inability to detect viable organisms in blood, synovial fluid or skin in a significant number of patients suggests that additional factors may be important. An immune mechanism has been postulated since immune complexes have been detected in culture-negative skin lesions and the synovium. Occasional occurrence of immune-mediated skin lesions such as erythema nodosum and erythema multiforme might further support this hypothesis.<sup>87</sup> Based on culture characteristics, patients with clinical manifestations of DGI are classified into proven, probable, and possible cases. Individuals with positive cultures from blood, joint fluid or skin lesions are considered to have proven DGI and constitute less than 50% of cases. Patients with negative cultures from distant sites but with proven infection of the urogenital tract, anorectal tract or the pharynx are considered probable DGI cases and constitute the majority of cases. Individuals presenting with the characteristic findings of DGI but with negative cultures are referred to as having possible DGI.<sup>21,85</sup>

The characteristic clinical findings include suppurative arthritis and skin lesions. Overt arthritis occurs in 30–40% of patients with DGI.<sup>84,85</sup> It is a purulent asymmetric polyarthritis with onset in the 3–4 weeks of infection and affecting females more commonly than males. Wrist, ankle, knee, and the metacarpophalangeal joints are commonly involved. The patient develops high-grade fever, severe joint pain with swelling, erythema, and limitation of movement. It leads to destruction of the articular surfaces, narrowing of the joint space and ankylosis. Aspiration of the synovial joint fluid usually reveals leukocyte count of 30,000–80,000 PMNL/mm<sup>3</sup> (average 40,000 PMNL/mm<sup>3</sup>) and gonococci may be demonstrated on microscopy and culture. Around 60% of patients present without a detectable synovial effusion and over 90% of these have an associated skin rash or tenosynovitis.<sup>88</sup>

Gonococcal dermatitis is usually the presenting feature of DGI. The rash reported in 59–77% of DGI cases presents as tender, necrotic pustules with irregular hemorrhagic border and erythematous base, involving the distal aspect of the limbs overlying the small joints, palms, and soles but sparing the scalp,

face, and mouth. The number of lesions ranges from about 5 to 20. Other morphological variants include macules, papules, pustules, bullae, petechiae or ecchymoses. These lesions are seen in the various stages of development and resolve in 3–4 days with residual brownish discoloration. The rash is associated with high-grade fever, arthralgia, and tenosynovitis. Gonococci can be occasionally demonstrated in cultures from skin lesions and more frequently by immunofluorescent staining methods.<sup>89</sup>

DGI is considered more common in females, and male to female ratio of 1:4 has been reported.<sup>90</sup> Gonococcal septicemia occurs 7–30 days after primary infection and commonly within 7 days following menstruation. The primary mucosal infection in DGI is usually asymptomatic with a low chance of developing concurrent epididymitis or PID. This may be the result of impaired PMNL chemotaxis and reduced complement system activation. This leads to less mucosal inflammation and a greater opportunity for hematogenous spread.<sup>90</sup> Pregnancy and the perimenstrual period are two other risk factors for DGI. This is at least partly due to associated changes in gonococcal phenotype from opaque (Opa expressing) to transparent (mainly Opa-; which is more resistant to the killing action of normal serum) in conjunction with alterations in vaginal pH, cervical mucus, and genital flora.<sup>84</sup> Pharyngeal gonorrhea is also associated with increased risk of DGI. The role of immunosuppression secondary to alcoholism, steroids, intravenous (IV) drug use or systemic lupus erythematosus is unclear but these may contribute to a small number of cases particularly those with recurrent episodes of DGI. Individuals with complement deficiency, especially of factors C7–C9, either inherited or acquired, are predisposed to DGI, since complement activation plays a central role in controlling the spread of *N. gonorrhoeae* by acting as a chemoattractant for PMNL, opsonizing bacteria, and via the antibody–complement-mediated bactericidal activity of serum.<sup>21,86</sup> Most of the DGI cases have been caused by strains of the AHU-auxotype,<sup>61,63</sup> that is also associated with asymptomatic urethral infection in men,<sup>62,85</sup> susceptibility to penicillin,<sup>61,63</sup> and resistance to complement-dependent bactericidal action of normal human serum.<sup>9,21,61,63</sup> Furthermore, PorB1a isolates have been associated with invasive disease like DGI, and this may be affected by the fact that PorB1a but not PorB1b also promotes Opa-independent invasion of epithelial cells, as well as possibly that they inhibit the complement system and chemotactic response.<sup>21,62,91</sup>

Hematological investigations reveal leukocytosis usually not exceeding 20,000/mm<sup>3</sup>, a raised ESR (>50 mm), anemia, and elevated transaminases. Gonococci are detected on blood culture in one-third of the cases and synovial fluid cultures are positive in half the patients with a purulent effusion. Cervical cultures are positive in 90% of women, urethral cultures in 50% of men, pharyngeal cultures in 20% cases, rectal cultures in 15% of cases, and skin cultures in approximately 5% of the patients.<sup>21,88</sup>

Complications of DGI include myocarditis, endocarditis, pericarditis, meningitis, anterior uveitis, hepatitis, and perihepatitis. Endocarditis occurs in approximately 1–3% of the patients with

DGI.<sup>85</sup> Death may occur as a result of aortic valve incompetence and congestive cardiac failure.<sup>89</sup>

## GONORRHEA IN PREGNANCY

Gonococcal infection may have a devastating impact on both the pregnant woman and the outcome of pregnancy. Prior to 7–12 weeks of gestation, there is a relatively high risk of developing salpingitis and PID. After this period, the chances of developing PID are less, mainly due to local cervical factors that are modified under the influence of progesterone. Cervical mucus becomes thick and impermeable to the gonococci and the high progesterone concentration inhibits the growth of *N. gonorrhoeae*. After the 12th week of gestation, the chorion gets attached to the endometrial decidua, thus obliterating the intrauterine cavity and preventing ascending infection. Under such circumstances, gonococcal chorioamnionitis may occur which leads to septic abortion. It also increases the risk of premature rupture of membranes, preterm births, prematurity, perinatal mortality, or low birth weight.<sup>92</sup> Following child-birth, approximately 47% of women with intrapartum gonorrhea have been shown to develop postpartum endometritis, salpingitis, and puerperal sepsis.<sup>93</sup>

The prevalence of pharyngeal gonorrhea is also higher in pregnant women. In approximately 15–35% of pregnant women with gonorrhea, the organism has been solely isolated from the throat. Pharyngeal infection also increases the risk of developing DGI during pregnancy.<sup>94</sup>

In order to prevent maternal complications and neonatal morbidity, all pregnant women and their sex contacts should be asked about past and present STD, counseled about the possibility of perinatal infections, and provided access to treatment, if needed. Furthermore, all women at risk (see risk factors above, however, these may vary in different settings) for gonorrhea or living in a high-prevalent setting should be screened during early pregnancy (first prenatal visit). Women found infected with gonorrhea during the first trimester should be promptly provided appropriate treatment and be retested within approximately 3–6 months, preferably in the third trimester. Furthermore, uninfected women who remain at high risk for gonorrhea should also be retested during the third trimester.<sup>24</sup> Notification and prompt treatment of sex contacts are imperative since reinfection has been reported in about 11–30% cases.<sup>95</sup>

## NEONATAL GONORRHEA

The most frequent manifestation is conjunctivitis (ophthalmia neonatorum).<sup>21</sup> The disease presents as a mucopurulent to purulent discharge that literally pours out when the eyelids are separated. Both the eyes are nearly always affected. The conjunctiva becomes intensely inflamed, bright red, and swollen with marked chemosis. There is dense infiltration of the bulbar conjunctiva initially that later becomes puckered and velvety with free discharge of pus, serum, and blood. A false membrane may form in a few cases resembling membranous conjunctivitis. Untreated cases

develop corneal ulcers over an oval area just below the centre of cornea. Rarely, oval marginal ulcers may form, followed by corneal perforation, iris prolapse, and extrusion of the lens. Other complications include anterior synechiae, adherent leukoma, partial or total anterior staphyloma, anterior capsular cataract, and panophthalmitis. Macular fixation may be impaired causing nystagmus. According to historical data, approximately 3% of neonates with untreated gonococcal ophthalmia neonatorum will develop complete blindness and 20% will develop some degree of corneal damage.

## GONORRHEA IN CHILDREN

Gonorrhea is more common in girls than in boys. Sexual abuse is the most common cause of gonorrhea in children and, according to a report from 1994, reported rates of gonococcal infection from case series range from 3% to 20%.<sup>96</sup> Potential non-sexual causes include sharing of bed or towels with infected parents, use of infected thermometers or contaminated toilet articles in hospital wards and orphanages. However, this type of non-sexual gonorrhea transmission is extremely rare and there are only a couple of confirmed cases described in the scientific literature. The most common manifestation in girls is vulvovaginitis since the non-cornified vaginal mucosa in the prepubertal age group is most susceptible to infection. It presents as vaginal itching, crusting and minimal discharge (that stains the undergarments), dysuria, vulval erythema, and edema. Ascending infection leading to salpingitis and PID with pelvic abscess is very rare. In boys, gonococcal urethritis similar to that in adults occurs and is usually associated with anorectal and tonsillopharyngeal colonization. DGI in the forms of arthritis, meningitis, endocarditis, myocarditis, conjunctivitis, and hepatitis is exceedingly rare in this age group.

## Diagnosis of Gonorrhea

Diagnosis of gonorrhea based solely on clinical manifestations is very difficult and is only suggestive. Accordingly, laboratory diagnostics is crucial for provision of gonorrhea diagnosis.

The presumptive diagnosis of gonorrhea by identification of characteristic intracellular Gram-negative diplococci within PMNL in Gram-stained smears (Fig. 39.8) remains the mainstay in many clinical settings, particularly for patients with the signs and symptoms of gonorrhea. This method is also simple, rapid, and cheap. However, the method is only sufficient to provide a definitive diagnosis (presence or absence of infection) for urethral gonorrhea in symptomatic men (specificity [ $>99\%$ ] and sensitivity [ $>95\%$ ]). In asymptomatic men, due to the substantially lower sensitivity (30–50%), a negative Gram stain of a urethral smear is not sufficient for excluding the possibility of gonorrhea. This is also true for Gram stain of endocervical specimens (30–50% sensitivity), pharyngeal specimens, and rectal specimens (40–60% sensitivity in blindly obtained specimens), due to the low sensitivity and also a sub-optimal specificity (in particular for pharyngeal specimens). Accordingly, Gram stain should not be used as the sole test for diagnosis of gonorrhea

**Fig. 39.8:** Gram-stained smear of urethral discharge (male) showing Gram-negative intracellular diplococci within polymorphonuclear leukocytes.

in these specimens. In some settings, methylene blue staining of smears is used, which is a simple, rapid, and useful method where laboratory facilities are not well-developed. However, compared to Gram staining this method has a lower specificity.<sup>17–21,24,26,97</sup>

Laboratory diagnosis of gonorrhea by sensitive and specific detection of *N. gonorrhoeae*, or its nucleic acid, is strongly recommended. Culture diagnostics of gonorrhea (Fig. 39.9) has historically been the gold standard method due to, in particular, its high specificity (100%; i.e., if appropriate species verifying tests are utilized) but also high sensitivity (80–>95%; i.e., dependent on anatomic sites sampled and optimizations of entire procedure), and providing opportunities for phenotypic characterization. Importantly, culture of *N. gonorrhoeae* is the

only diagnostic method that allows testing of antimicrobial susceptibility, which is essential to monitor the emergence of resistance to current therapies. However, for a high sensitivity and specificity each step of the culture diagnostics requires to be optimized, including specimen collection, specimen transportation medium, and transportation (if bed side culture, which is ideal, is not performed), inoculation and incubation of cultures, and subsequent use of appropriate species verifying assays for *N. gonorrhoeae*. A selective culture medium, ideally combined with a non-selective medium, should be used. Many effective selective culture media have been developed, such as Modified Thayer–Martin (MTM), Martin–Lewis (ML), New York City (NYC) and GC-Lect (GC–L) medium, which are composed of GC agar base or equivalent media supplemented with growth factors and antimicrobial agents to inhibit growth of other bacteria or fungi. These selective media commonly include vancomycin (or lincomycin), colistin, nystatin (or amphotericin B), and trimethoprim to inhibit Gram-positive bacteria, non-gonococcal Gram-negative bacteria, fungi, and swarming *Proteus* species, respectively. Furthermore, appropriate species verification of *N. gonorrhoeae* should be performed, including identification of Gram-negative diplococci in microscopy, rapid oxidase production (Fig. 39.10), and at least one species verifying assay, such as carbohydrate utilization test (Fig. 39.11), rapid biochemical or chromogenic enzyme substrate tests, co-agglutination test (e.g., Phadebact Monoclonal GC Test) (Fig. 39.12), immunofluorescence assay (e.g., MicroTrak *N. gonorrhoeae* culture confirmation test) (Fig. 39.13), or molecular test (NAH test or NAAT).<sup>17–21,23,24,26,97</sup>

During the recent decades, molecular detection (NAH tests and, in particular, NAATs) for *N. gonorrhoeae* has been rapidly

**Fig. 39.9:** Characteristic colonies of *Neisseria gonorrhoeae* grown on New York City culture medium.

**Fig. 39.10:** Rapid oxidase production of gonococcal colonies displayed directly on culture medium.

**Fig. 39.11:** Carbohydrate utilization test (Cystine Trypticase Agar [CTA] test) showing *Neisseria gonorrhoeae* degrading glucose (yellow) but not maltose (pink) or sucrose (pink).

**Fig. 39.12:** Co-agglutination test (Phadebact Monoclonal GC Test) of one *Neisseria gonorrhoeae* strain (no. 2, showing typical co-agglutination) and one *N. meningitidis* strain (no. 1, no co-agglutination). No. 5 and 6 are positive control and negative control, respectively.

replacing the culture diagnostics in many settings. Especially the NAATs offer highly sensitive and specific detection. The molecular tests are also more tolerant of delays or inadequacies in collection or transportation of specimens, more rapid, can be highly automated, and commonly can detect *N. gonorrhoeae* and *C. trachomatis* simultaneously. Furthermore, NAATs allow testing of also non-invasive specimens (including self-collected specimens), such as vaginal swabs and urine, while culture and NAH tests require invasive specimens, such as endocervical swab from women and urethral swab from men. There are many different NAATs commercially available, which use divergent

**Fig. 39.13:** Immunofluorescence assay (MicroTrak *N. gonorrhoeae* Culture Confirmation Test) showing characteristic fluorescent gonococci.

methods for amplification of a *N. gonorrhoeae* specific DNA or rRNA sequence, i.e., polymerase chain reaction (PCR; Roche diagnostics and Abbott Laboratories), strand displacement amplification (SDA; Becton Dickinson), and transcription-mediated amplification (TMA; Gen-Probe). The sensitivity of these NAATs in both urogenital and extragenital anatomic sites is superior to culture, but the performance characteristic, including sensitivity and specificity, varies with the type of NAAT assay.<sup>17,19,21–25,97–104</sup> No commercial NAAT is licensed by any regulatory body for detection of *N. gonorrhoeae* in rectal, pharyngeal, and conjunctival specimens. Nevertheless, as detection of the gonococci by NAATs usually is more sensitive compared to culture, some laboratories offer these tests for diagnosis of gonorrhea and some laboratories have also established their own performance specifications for using NAAT with rectal and pharyngeal swab specimens, thereby allowing results to be used for clinical management.<sup>24,97–101</sup> However, many of the gonococcal NAATs have been shown to cross-react with other non-gonococcal *Neisseria* species, e.g., *N. cinerea*, *N. flavescens*, *N. lactamica*, *N. subflava*, and *N. meningitidis*. These commensal *Neisseria* species and *N. meningitidis* can frequently inhabit extragenital sites, in particular oropharynx, and may result in false positive clinical reports. This sub-optimal specificity displayed by some of the NAATs may cause a very low positive predictive value (PPV), especially in setting with low prevalence of gonorrhea. Accordingly, laboratories that use NAATs for gonorrhea diagnostics, in particular if also extragenital specimens are examined, must ensure that specificity is not compromised by cross-reaction with non-gonococcal *Neisseria* species, and should sometimes consider to use an additional or supplemental assays to ensure definitive and confirmed diagnosis of gonorrhea.<sup>24,25,102–104</sup> The latest generation of gonococcal NAATs, however, displays a substantially higher specificity. It is also important to keep in mind that the results of the NAATs must be interpreted carefully in the context of diagnosis, due to the fact that *N. gonorrhoeae* DNA, which usually is eliminated 2–3 days after successful treatment, may in rare cases be present in specimens

for up to 2–3 weeks.<sup>17,26,105</sup> Because molecular tests (NAH tests or NAATs) cannot provide antimicrobial susceptibility results, in cases of suspected or verified clinical treatment failure, culture and antimicrobial susceptibility testing should always be included in the diagnostics. Other disadvantages with NAATs include the need for expensive equipment and diagnostic reagents, appropriate laboratory facilities and training, and the risk of contamination by previously amplified nucleic acid.<sup>17,19,21–26,97,102–104,106</sup>

## Antimicrobial Treatment of Gonorrhea

Effective treatment of gonorrhea is defined as the elimination of *N. gonorrhoeae* from all anatomic sites.<sup>107</sup> Single dose oral therapy has historically been preferred for high compliance and ease of administration. An antimicrobial recommended for first-line treatment of gonorrhea should treat >95% of the patients with uncomplicated urogenital and anorectal infection.<sup>5,26</sup> Due to the lack of adequate clinical studies for the currently used therapeutic options, nowadays the first-line antimicrobials are commonly recommended to be replaced when  $\geq 5\%$  of the gonococcal strains in the general population are resistant.<sup>5,26</sup> When initially introduced for treatment, many antimicrobial agents were highly effective against *N. gonorrhoeae*, wild type is inherently susceptible to many antimicrobials. However, during the last 70–80 years, *N. gonorrhoeae* has developed resistance to mainly all antimicrobials introduced for treatment of gonorrhea. In most cases, resistance has emerged and spread internationally only a few decades after introduction of the antimicrobial. Worryingly, the antibiotic treatment options now seem to be running out, and in near future gonorrhea may become untreatable in certain circumstances (see below).<sup>4,5</sup>

In general, antimicrobial resistance shows geographical variation, some antimicrobials have lower efficacy at extragenital sites (especially oropharynx), some are contraindicated under special circumstances, such as pregnancy or neonatal period and some are not affordable in less-resourced settings. Most of the old clinical trials were mainly studying treatment of uncomplicated urogenital gonorrhea. There are far less clinical data and also pharmacodynamic data available regarding the treatment of anorectal or pharyngeal infection, and there is a dearth of reports on the treatment outcome of complicated infection.

## DRUG TREATMENT AND RESISTANCE IN *N. GONORRHOEA*

### History

Before chemical and antimicrobial therapies were introduced, therapies such as urethral astringents, soundings, and mechanical devices were used for treatment of gonorrhea. In regard to chemical therapies, injection of mercury via the urinary meatus was used before urethral irrigation with potassium permanganate solution and the widely used silver nitrate were introduced in the late 1800s.<sup>27,108</sup> Protargol (a colloidal silver compound) was introduced in 1897, and it rapidly replaced silver nitrate. Protargol

was used mainly until the introduction of the first antimicrobials, i.e., the sulfonamides in 1936.<sup>27,28,109,110</sup> The sulfonamides were initially very effective. However, within 6–8 years, in some settings, >75% of the gonorrhea patients carried gonococci resistant to sulfonamides.<sup>27,28,109,110</sup> Fortunately, already in 1943 penicillin was shown to be highly effective for treatment of gonorrhea.<sup>29</sup>

### Penicillins

The introduction of penicillin for treatment of gonorrhea in 1943<sup>29</sup> led to virtual abandonment of sulfonamides and single, low-dose treatment with penicillin became the standard treatment. Remarkable cure rates were achieved, however, within 10–15 years a steady decrease in the penicillin susceptibility resulting in clinical treatment failures was observed.<sup>110</sup> The decreasing penicillin susceptibility was from the 1950s until the mid-1970s met by using escalating doses and combining penicillin with probenecid.<sup>111,112</sup> This gradual decrease in penicillin susceptibility was due to the sequential accumulation of chromosomal resistance mutations (see below).<sup>109</sup> The extended-spectrum penicillins, such as ampicillin, amoxicillin, ticarcillin, piperacillin, and mezlocillin, showed high activity against *N. gonorrhoeae*<sup>113</sup> and some of these (especially ampicillin and amoxicillin) were included in the regimens for treatment in many settings worldwide. In 1976, two types of  $\beta$ -lactamase encoding plasmids, originating in Asia and Africa, causing high-level penicillin resistance were reported in *N. gonorrhoeae*.<sup>34,35</sup> These  $\beta$ -lactamase producing strains spread internationally; however, they remained in low prevalence for several years in many geographical regions worldwide. Accordingly, it was mainly after the discovery and characterization of the first strain causing penicillin-resistant gonorrhea due to chromosomal mutations only<sup>109,114</sup> and the subsequent spread of these strains that penicillin was abandoned as first-line treatment. For instance, surveillance data from the USA in 1989 reported significant and sustained resistance to all the penicillins, and these were no longer recommended.<sup>115</sup> At present time, the level of resistance to penicillins is high in most countries worldwide.<sup>3,5</sup> Already in the late-1940s to 1960s other antibiotics were used in the treatment of gonorrhea for those patients where penicillin was contraindicated; these alternative antibiotics included certain aminoglycosides and tetracycline.

### Tetracyclines

Tetracyclines have been important and effective antimicrobial agents in the treatment of several STDs, and previously these were also used for treatment of gonorrhea in many countries. However, tetracycline resistance, both chromosomally and plasmid mediated, emerged and rapidly spread internationally, and is nowadays high in most countries worldwide.<sup>3,5</sup> In the USA and Western Europe, tetracyclines have not been recommended for treatment of gonorrhea since the late-1980s.

## Spectinomycin

Spectinomycin (an aminocyclitol) played a central role in the control of gonococcal infection following emergence of PPNG and high-level chromosomally mediated penicillin resistance.<sup>114</sup> It was shown effective in clinical trials, curing 98.2% of uncomplicated urogenital and anorectal gonococcal infections (single intramuscular [IM] dose of 2 g), and safe in pregnancy. However, spectinomycin has poor efficacy against pharyngeal infection (51.8%; 95% CI = 38.7–64.9%).<sup>24,107</sup> Spectinomycin was used as first-line treatment for the USA military personnel in Korea and the gonococci quickly developed resistance.<sup>116</sup> Nevertheless, spectinomycin resistance seems unstable, reverts once its use is discontinued and consequently at present time spectinomycin resistance is rare worldwide.<sup>3–5</sup> Unfortunately, spectinomycin, which would be valuable for treatment of patients who cannot tolerate cephalosporins and cephalosporin-resistant gonorrhea, is not available in many settings worldwide.

## Fluoroquinolones

Fluoroquinolones became popular and proved effective as first-line treatment from the mid-1980s or early-1990s, and onwards in many countries. They were also effective in eradicating anorectal and pharyngeal infection, and safe in individuals allergic to  $\beta$ -lactam antimicrobials. However, the fluoroquinolones are contraindicated for use in pregnancy, children, and growing adults. Ciprofloxacin has been the most widely used fluoroquinolone, but also ofloxacin has been commonly administered in many countries. A single oral dose of 500 mg ciprofloxacin was well-tolerated and very effective. Ofloxacin 400 mg orally in a single dose and norfloxacin given in a single dose of 800 mg were also effective.<sup>117</sup> Unfortunately, clinically resistant strains emerged, they were transmitted in South-East Asia already in the mid-1990s,<sup>118</sup> and soon they were spreading worldwide. Due to the high prevalence of ciprofloxacin resistance, many Asian and European countries excluded ciprofloxacin as first-line treatment in the early- or mid-2000s. By 2007, fluoroquinolone-resistant strains were of such high prevalence throughout the USA that all fluoroquinolones were removed from the recommended treatment regimen.<sup>109,119</sup> At present time, the level of ciprofloxacin resistance is high in most countries worldwide, i.e., where adequate surveillance has been performed.<sup>3,5</sup>

## Azithromycin

Azithromycin is a relatively new macrolide (azalide class). The oral dose of azithromycin displays a higher absorption as compared to the previously used erythromycin due to its greater stability in the gastric acid, and so it achieves a higher and more sustained intracellular concentration. A single 1 g oral dose of azithromycin is an effective and frequently recommended therapy against urogenital *C. trachomatis* infection.<sup>24</sup> According to a recent review, using single dose azithromycin therapy has also shown aggregated cure rates for urethral and endocervical gonorrhea

of 96.5% for a 1 g dose and 99% for a 2 g dose. Furthermore, azithromycin cured 97.9% cases of oropharyngeal infection and 97.1% cases of anorectal infection evaluated within these clinical trials.<sup>120</sup> However, several studies have documented treatment failures using 1 g of azithromycin and emergence of resistance may be more rapid using this lower dose.<sup>121–123</sup> The disadvantages of using azithromycin for treatment of gonorrhea include its cost, high frequency of gastrointestinal side-effects (but these are less frequent with the new formulation of azithromycin available in some countries), and in particular the fear of rapid development of resistance. The resistance level has also increased rapidly and high-level azithromycin-resistant gonococcal isolates have been identified in several countries.<sup>5</sup> Due to this concern regarding rapid emergence of resistance, widespread or first-line use of azithromycin as sole antimicrobial therapy for gonorrhea has never been recommended. However, azithromycin can be valuable for treatment of gonococcal infections from any site in persons with severe allergic reactions to  $\beta$ -lactam antimicrobials, in some other specific clinical situations and in combination therapy, i.e., with extended-spectrum cephalosporins in the treatment of both gonorrhea and *C. trachomatis* infection and possibly in future combination therapy for ceftriaxone-resistant gonorrhea.

## Cephalosporins

Extended-spectrum cephalosporins have, in several decades, proved highly efficacious for treatment of urogenital, anorectal, and pharyngeal gonorrhea worldwide. The injectable ceftriaxone or oral cefixime are the most potent and usually recommended extended-spectrum cephalosporins for treatment of gonorrhea.<sup>3–5,24</sup>

Ceftriaxone, because of its high intrinsic potency, long half-life (6–9 hours) and lack of resistance in circulating gonococcal strains, is currently the most potent gonorrhea antimicrobial for a single dose regimen.<sup>3,5,24</sup> Clinical experience has shown that ceftriaxone is safe, including in pregnancy and neonates, and effective for the treatment of gonorrhea at any anatomic site, displaying cure rates of 99.2% for uncomplicated urogenital and anorectal, and 98.9% for pharyngeal infections in clinical trials.<sup>24,107,124</sup> Alternative parenteral single-dose regimens for urogenital and anorectal gonorrhea include ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g orally, or cefotaxime 500 mg IM.<sup>24,125</sup> However, none of these injectable cephalosporins offer any advantages over ceftriaxone for urogenital and anorectal infection, and efficacy for pharyngeal infection is less certain.<sup>24,107,124</sup> The main drawback with ceftriaxone is its high cost in several settings and parenteral mode of administration.

Cefixime is an oral preparation with similar spectrum as ceftriaxone and a single 400 mg oral dose has been shown to be nearly as effective as the injectable ceftriaxone against uncomplicated urogenital and anorectal gonorrhea. However, cefixime (400 mg oral dose) does not provide as high, nor as sustained, a bactericidal level as that provided by ceftriaxone (250 mg IM dose). In clinical trials, cefixime (400 mg oral dose) cured 97.5% of uncomplicated urogenital and anorectal (95% CI = 95.4–99.8%), and only 92.3% of pharyngeal gonococcal

infections (95% CI = 74.9–99.1%).<sup>24,107,124,126,127</sup> Accordingly, especially for some cases of pharyngeal gonorrhea cefixime (400 mg oral dose) may be sub-optimal.

Worryingly, in recent years susceptibility to these recommended first-line antimicrobials, i.e., ceftriaxone and cefixime, has decreased globally.<sup>3–5</sup> Cefixime treatment failures have been verified in Japan since several years,<sup>4,5,128,129</sup> and recently the first clinical failures were confirmed in Europe.<sup>130</sup> Given history, it is most likely that cefixime resistance will continue to spread globally and also ceftriaxone will have the same fate. Previously, only three cases of treatment failures of pharyngeal gonorrhea using ceftriaxone have been verified,<sup>131,132</sup> but these clinical failures were most likely affected by the known difficulties in treating pharyngeal gonorrhea compared with urogenital infection. Due to pharmacodynamic parameters, few (if any) antimicrobial agents can reliably cure all cases of pharyngeal gonorrhea infections.<sup>5,107,124,131</sup> Nevertheless, recently the fear of emergence of ceftriaxone resistance in *N. gonorrhoeae* was justified with the emergence and detailed characterization of the first gonococcal strain displaying high-level clinical resistance to ceftriaxone (MIC of 2–4 µg/mL), identified in Japan.<sup>4</sup> This is particularly worrisome as ceftriaxone is the last remaining option for empirical first-line treatment of gonorrhea. *N. gonorrhoeae* seems to be evolving into a true “superbug” and, gonorrhea may become untreatable in certain circumstances and especially in some settings.

## Future Management of Gonorrhea

A serious public health problem in which case gonorrhea may become untreatable in certain circumstances and, in particular, some settings may be approaching. To at least restrain the spread of cefixime and ceftriaxone resistance, timely public health multi-disciplinary and multi-component actions are imperative. A recent expert review described WHO initiatives to antimicrobial resistance containment and how to meet the public health challenges of emergence and spread of multi-drug resistant (MDR) *N. gonorrhoeae*, extensively-drug resistant (XDR) *N. gonorrhoeae*, and untreatable gonorrhea.<sup>5</sup> WHO has also recently launched a global gonococcal antimicrobial susceptibility programme (WHO Global-GASP), for enhanced and quality assured monitoring of antimicrobial resistance in *N. gonorrhoeae* worldwide.<sup>5,133</sup> However, all these actions will likely not be able to prevent the emergence, establishment and spread of cefixime and ceftriaxone resistance, but only delay the global spread of the resistance. Ultimately, a major focus important for public health globally is to timely develop new effective drugs (for single or combined use) and/or novel strategies for the treatment of gonorrhea, and ideally an effective vaccine.<sup>4,5</sup>

## Molecular Mechanisms for Resistance to Relevant Antimicrobials in *N. gonorrhoeae*

The resistance of *N. gonorrhoeae* to many antimicrobials, acquired by intrastrain mutations and/or interstrain transfer of DNA

by conjugation or transformation, is widespread and occurs as chromosomally mediated resistance to a variety of antibiotics and high-level plasmid-mediated resistance to penicillins and tetracyclines. The chromosomally mediated resistance usually develops slower and, for several antibiotics, this resistance is due to the cumulative effects of different mutations that decrease the affinity of the antimicrobial for its target molecule, increase the efflux of antimicrobials through efflux pumps, and/or decrease the intake of antimicrobials.<sup>5,26</sup>

### Penicillin Resistance

**Chromosomally Mediated Resistance** Gonococcal strains that require ≥2 mg/L of penicillin for inhibition and do not produce β-lactamase are designated as chromosomally mediated penicillin-resistant *N. gonorrhoeae* (CMRNG). This type of resistance is caused by the stepwise cumulative effects of mutations at multiple loci, including *penA* (mutations cause a decreased affinity of penicillin for its lethal target, the encoded penicillin binding protein 2 [PBP2]), *mtrR* promoter or coding region (mutations cause an overexpression of the MtrCDE efflux pump, which actively pumps the antimicrobial out of the cell), and *porB1b* (the “*penB*” resistance determinant that causes a decreased intake of antimicrobial through the porin PorB). In addition, one specific mutation in *ponA* causes a decreased affinity of penicillin for the encoded PBP1 (second target for penicillin), and further decreased susceptibility to penicillin. Moreover, the *penC* (currently named *pilQ2*) mutation in the *pilQ* gene, which encodes the secretin PilQ of the type IV pilin, inhibits the entry of penicillin in the bacterial cell and, accordingly, further decrease the susceptibility to penicillin. However, *pilQ2* mutations impact proper piliation, which is important for gonococcal disease and transmission of infection, and accordingly this mutation may not be of importance for wide spread of clinical penicillin resistance. Finally, at least one additional, non-transformable resistance determinant exists, the so-called “Factor X.”<sup>4,5,109,134–136</sup>

**Plasmid-Mediated Resistance** The high-level resistance to penicillin in PPNG is attributed to the production of the enzyme β-lactamase (penicillinase) via single-step acquisition of β-lactamase encoding plasmids (see above). β-lactamase hydrolyses the cyclic amide bond in the β-lactam ring of β-lactamase instable penicillins, converting the penicillin into inactive penicillinoic acid.

### Spectinomycin Resistance

Specific single nucleotide polymorphisms (SNPs) in the *16S rRNA* gene, which result in a decreased affinity of spectinomycin for its 16S rRNA target, mediate high-level resistance to spectinomycin.<sup>137</sup>

### Fluoroquinolone Resistance

The high-level resistance in quinolone-resistant *N. gonorrhoeae* (QRNG) is due to cumulative effect of multiple mutations in specific regions (quinolone resistance determining regions

[QRDR]) of the *gyrA* and *parC* genes that encode the subunits GyrA and ParC of the target enzymes DNA gyrase and topoisomerase IV, respectively.<sup>109,138</sup>

### Macrolide Resistance

Resistance to azithromycin and/or erythromycin can be caused by mutations in the *mtrR* promoter or coding sequence (result in an overexpression of the MtrCDE efflux pump), presence of the *mef* (*A*) encoded efflux pump (enhances the efflux of macrolides), presence of one or several *erm* genes encoding 23S rRNA methylases (modify the ribosomal target), or specific SNPs in one or several of the four genomic alleles encoding 23S rRNA (reduce the affinity of the macrolide for its ribosomal target).<sup>109,139</sup> The exceedingly high-level azithromycin resistance recently identified in some countries has been due to specific SNPs in several of the four alleles of the 23S rRNA gene.<sup>5,123,140</sup>

### Cephalosporin: Decreased Susceptibility and Resistance

The  $\beta$ -lactamase produced by PPNG, which degrades penicillins, is not affecting the extended-spectrum cephalosporins and fortunately *N. gonorrhoeae* has yet not developed or acquired any extended-spectrum  $\beta$ -lactamase (ESBL). Accordingly, the decreased susceptibility and resistance to extended-spectrum cephalosporins in *N. gonorrhoeae* are chromosomally mediated, and the mechanisms are similar to the mechanisms causing chromosomally mediated resistance to penicillins (see above). The most common mechanism in *N. gonorrhoeae* for decreased susceptibility or resistance to extended-spectrum cephalosporins is *penA* alteration, i.e., acquisition of a *penA* mosaic allele or A501 alterations in PBP2. However, the effects of different *penA* mosaic alleles on the susceptibility to extended-spectrum cephalosporins substantially differ and many new *penA* mosaic alleles are emerging. Mutations in the promoter and/or coding sequence of *mtrR* cause an over-expression of the MtrCDE efflux pump system, which further decreases susceptibility to the extended-spectrum cephalosporins. The *penB* resistance determinant (see above) results in additionally decreased susceptibility to the extended-spectrum cephalosporins. Alterations in PBP1 and PilQ (involved in chromosomally mediated penicillin resistance) do not seem to substantially affect the susceptibility to the extended-spectrum cephalosporins in presently circulating strains. Finally, at least one additional, non-transformable resistance determinant exists, the so-called "Factor X."<sup>4,5,109,134–136,141</sup>

### CURRENTLY RECOMMENDED TREATMENT REGIMENS FOR GONORRHEA

The recommended treatment regimens for uncomplicated gonorrhea according to the Sexually Transmitted Diseases Treatment Guidelines, 2010 from CDC, USA<sup>24</sup> and the 2009 European (IUSTI/WHO) guidelines on the diagnosis and treatment of gonorrhea in adults<sup>127</sup> are summarized in Table 39.2.

**Table 39.2:** The Recommended Treatment Regimens for Uncomplicated Gonococcal Infections According to the Sexually Transmitted Diseases Treatment Guidelines, 2010 from CDC, USA<sup>24</sup> and the 2009 European (IUSTI/WHO) Guidelines<sup>127</sup>

#### Uncomplicated Gonococcal Infections of the Cervix, Urethra, and Rectum in Adults and Adolescents

##### Recommended regimens

**Ceftriaxone** 250 mg in a single intramuscular (IM) dose<sup>24,127</sup>

OR (IF NOT AN OPTION<sup>24</sup>)

**Cefixime** 400 mg in a single oral dose<sup>24,127</sup>

OR

**Cephalosporin regimens** in a single injectable dose<sup>24,a</sup>

**Spectinomycin** 2 g in a single IM dose<sup>127</sup>

**PLUS<sup>24,127,b</sup>**

**Azithromycin** 1 g in a single oral dose

OR

**Doxycycline** 100 mg a day for 7 days

#### Uncomplicated Gonococcal Infections of the Pharynx

##### Recommended regimens

**Ceftriaxone** 250 mg in a single IM dose<sup>24,127</sup>

**PLUS<sup>24,b</sup>**

**Azithromycin** 1 g in a single oral dose

OR

**Doxycycline** 100 mg a day for 7 days

<sup>a</sup>Other cephalosporin regimens in a single injectable dose that are safe and effective include ceftizoxime 500 mg IM; cefoxitin 2 g IM, administered with probenecid 1 g orally; or cefotaxime 500 mg IM. However, none of these injectable cephalosporins offer any advantages over ceftriaxone for urogenital or anorectal infection, and efficacy for pharyngeal infection is less certain.<sup>24,107,124</sup>

<sup>b</sup>Treatment for gonorrhea should routinely be followed with effective treatment for concomitant *C. trachomatis* infection unless a sensitive diagnostic test has excluded co-infection.<sup>127</sup>

For alternative treatment regimens, treatment of gonococcal ocular infection (conjunctivitis in adults and ophthalmia neonatorum), disseminated gonococcal infection (DGI), salpingitis, and pelvic inflammatory disease (PID), see references 24 and 127.

### FOLLOW-UP AFTER TREATMENT

Partner notification is recommended for evaluation and treatment of sexual contacts. Test of cure is not recommended routinely for patients with uncomplicated gonorrhea who have been treated with recommended regimen(s). However, persons with persistent symptoms or whose symptoms recur shortly after treatment with a recommended regimen should be reevaluated by culture for *N. gonorrhoeae*; positive isolates should undergo antimicrobial susceptibility testing.

### Prevention of Gonorrhea

The first effective prophylaxis against gonococcal infection was described in 1881 by Karl Credé, who administered silver nitrate eye drops to neonates to prevent ophthalmia neonatorum.<sup>142</sup> No effective vaccine for gonorrhea has so far been developed, despite 3–4 decades of research in which whole organisms, purified components: pilus, transferring-binding proteins (TbpA/B), PorB-enriched outer membrane, etc., and some recombinants proteins

(PorB, including purified from Rmp-negative gonococci) have been evaluated as potential vaccine candidates. Major concerns have been raised regarding the mostly local, relatively low and unpersistent immune response after uncomplicated gonorrhea, i.e., poor protection causing possibilities of reinfection even with the identical gonococcal strain. The major concerns regarding the development of an effective gonococcal vaccine include (i) generation of non-bactericidal blocking antibodies (e.g., against Rmp) that block binding and activity of bactericidal antibodies (e.g., against PorB and LOS); (ii) sialylation of *N. gonorrhoeae* that facilitates binding of alternative complement regulator, factor H; (iii) possible elicitation of gonococcal IL-17 responses that suppress Th1/Th2 adaptive immune responses to natural infection; (iv) high level of antigenic heterogeneity in *N. gonorrhoeae*, the rapid antigenic variability, and phase variations (on/off switching) in the expression of, e.g., pili, Opa proteins and LOS; and (v) lack of an ideal animal model for this human specific pathogen (but novel transgenic mice expressing human genes required for gonorrhea should enable future vaccine research).<sup>55,143,144</sup> A polyvalent vaccine containing multiple antigenic epitopes of a single or several molecules may be needed. By using the new approach of “reverse vaccinology” not previously described conserved and immunogenic outer membrane proteins that can be potential vaccine candidates may also be identified based on the available *N. gonorrhoeae* genomes.

At present time, to reduce the incidence of gonorrhea, effective and accessible diagnostics; antibiotic treatment and contact tracing; screening for asymptomatic individuals; surveillance of the epidemiological characteristics and especially the antibiotic susceptibility of the bacteria, and the affected populations or sub-population (to identify risk behaviors and risk groups), to develop improved control measures and interventions are crucial. In addition, widespread education concerning sex, the transmission of infection, and the importance of use and availability of condoms that may result in changed and more protected sexual behavior is important, as are targeted preventions and interventions for high-risk groups.

# Chlamydia Trachomatis Infections

Nicola Steedman

# 40

## Introduction

*Chlamydia trachomatis*, a small gram-negative intracellular bacterium, is the most common bacterial sexually transmitted infection worldwide in the present day.<sup>1</sup> It can infect both men and women and produces no symptoms in a proportion of hosts hence providing an ongoing reservoir for continued infection.<sup>2</sup> Chlamydial infections can, however, have serious consequences for the host. In man *Chlamydia trachomatis* is the leading cause of preventative blindness on a global scale through the disease known as trachoma.<sup>3</sup> In its sexually transmitted form *C. trachomatis* infection causes urethritis and epididymo-orchitis in man and it is a leading cause of pelvic inflammatory disease, ectopic pregnancy, and infertility in women.<sup>4,5</sup> In addition, chlamydial infection can be passed from mother to neonate during parturition causing nongonococcal ophthalmia neonatorum and pneumonia.<sup>6</sup> Chlamydial conjunctivitis may in fact be found in all age groups and chlamydial proctitis can occur in both men and women as a result of anal intercourse.<sup>7</sup>

The relatively late isolation and identification of this organism is a result of its intracellular lifecycle and historically has impeded knowledge about and research into this important pathogen.

## History

Sexually transmitted diseases were initially considered more as clinical syndromes rather than caused by specific individual organisms and the discovery of *C. trachomatis* was prompted more by exclusion than anything else. Following the successful identification of the organism *Neisseria gonorrhoeae* in the late 19th century, it became apparent that urethritis in men and conjunctivitis in neonates occurred when *N. gonorrhoeae* was not present, suggesting the existence of other causative organisms.<sup>8</sup> Chlamydial intracellular inclusions were noted during light microscopy of clinical specimens from the 1900s and the lymphogranuloma venereum (LGV) organism was recognized first, however it was not until the late 1950s that *C. trachomatis* biovar *trachoma* was successfully isolated.<sup>9</sup> This was at least in part a result of the fact that *C. trachomatis* cannot be cultured

by conventional methods and required the development of a culture system involving yolk sac inoculation of embryonated hens' eggs.<sup>10</sup> The subsequent evolution of laboratory cell culture methods allowed more widespread testing of clinical specimens and prompted the suggestion that the organism was a cause of nongonococcal urethritis (NGU) in men. Studies in the 1970s confirmed isolation rates of around 50% in men with NGU compared with less than 5% in control subjects and concordance was established with sexual partners, confirming sexual transmission of *C. trachomatis* and its likely etiological role in NGU.<sup>1,11</sup>

It was originally thought by some that *C. trachomatis* must be a virus as it was discovered to be filterable and to be an obligate intracellular pathogen for its replication. It was, however, Sir Samuel Bedson and coworkers who correctly identified bacteria-like binary fission as the mechanism of chlamydial replication and reclassified the organism as bacterial. It was Bedson who isolated and characterized *Chlamydia psittaci* as the agent of psittacosis in the early 1930s and chlamydial organisms were known as Bedsonia initially in recognition of this work.<sup>12</sup> Subsequent titles for the *Chlamydia* genus included the psittacosis-lymphogranuloma-trachoma group (PTL organisms) and the trachoma-inclusion conjunctivitis organisms (TRIC group) before three separate species of *Chlamydia* were recognized within the genus: *C. psittaci*, *C. pneumoniae*, and *C. trachomatis*. The word chlamys comes from the Greek, meaning "cloak draped around the shoulder." This describes how the intracytoplasmic inclusions caused by the bacterium are "draped" around the infected cell's nucleus (Fig. 40.1).

In 1999 the single genus, *Chlamydia*, was reclassified into two different genera; *Chlamydia* and *Chlamydophila* (Fig. 40.2).<sup>13</sup> In addition to genetic and protein sequence differences with the genus *Chlamydia*, *Chlamydophila* spp. do not produce detectable glycogen and have one ribosomal operon whereas *Chlamydia* spp. have two. As a result of the chlamydial reclassification five new species were validated and the former *C. pneumoniae*, *C. pecorum*, and *C. psittaci* were moved to the new genus *Chlamydophila*. In this way the genus *Chlamydia* now consists of three species. The

**Fig. 40.1:** Cell infected with *Chlamydia trachomatis* showing classic perinuclear 'draped' inclusion body.

first of these is *Chlamydia trachomatis* (comprising the two human biovars: trachoma and LGV). The mouse and swine strains that were previously grouped with this species now belong to separate species (*C. muridarum* and *C. suis*, respectively).

The genus *Chlamydophila* consists of six species. The first of these is *Chlamydophila psittaci*, which primarily infects birds.

The former 'mammalian' *Chlamydia psittaci* abortion, feline, and guinea-pig strains have now been reclassified as three new species (*C. abortus*, *C. felis*, and *C. caviae*). The species *Chlamydia pecorum* has been renamed *Chlamydophila pecorum*. *C. pecorum* strains are generally noninvasive in a mouse model of virulence and are serologically and pathogenically diverse, having been isolated only from mammals. Finally *Chlamydia pneumonia* has been reclassified as *Chlamydophila pneumoniae*. Although it was formerly thought to be a specific human pathogen, it is now thought that *C. pneumoniae* can infect horses, koala, and other animals.<sup>14</sup>

## Biology

*C. trachomatis* is a gram-negative bacterium which exists as an obligate intracellular parasite with a lifecycle consisting of two distinct phases with two morphological forms. In the first of these the organism exists as small elementary bodies (EB) which are the infectious form of the bacterium. EB attach to cells and enter them before changing into the more metabolically active form, the reticulate body (RB). The larger RB is responsible for replication of the organism and the intracellular inclusions that can be seen under light microscopy. Following replication by binary fission, RB change morphologically back to EB which are finally released from the cell as new infectious agents (Fig. 40.3).

EB are spherical structures approximately 200–350 nm in diameter which closely adhere to the host cell surface and attachment appears to be aided by heparin sulfate-like molecules.

**Fig. 40.2:** Chlamydial taxonomy. The 1999 reclassification. Adapted from: Bush RM and Everett KDE. Molecular Evolution of the Chlamydiaceae. *Int J Syst Evol Microbiol* 2001;51:203–20.

**Fig. 40.3:** Life cycle of *Chlamydia trachomatis*. EB, elementary body; RB, reticulate body.

Endocytosis is the mechanism by which the EB enters the cell and although specific cell surface receptors responsible for this process have not yet been elucidated, various EB surface structures have been purported to be involved including major outer membrane proteins (MOMP) and in particular the cysteine-rich protein OmcB.<sup>15,16</sup> The endocytic process appears to involve elements of both phagocytosis and pinocytosis and results in the internalization of the EB within a cell membrane lined vesicle within the cell cytoplasm. Although the vesicles pass through the usual early maturation stages to become early endosomes and late endosomes, it appears that the expression of chlamydial gene products prevents subsequent fusion with lysosomes and therefore protects the endosome from lysis. Instead of fusing with lysosomes, the chlamydial endosome intersects vesicles destined for the exocytic pathway while chlamydial particles within undergo the process of morphological change from EB into RB.<sup>16</sup> This change occurs within 6–9 hours of chlamydial ingestion by the cell and is marked by the notable increase in size of the cellular inclusion body. RB are larger (1000 nm diameter) particles than EB and essentially are structurally gram-negative bacteria. They proceed to multiply by binary fission producing RNA, DNA, and protein while the chlamydial endosome is tracked, potentially via microtubules, to the cellular Golgi apparatus. Within 36 hours the lifecycle is complete. The metabolically active RBs which cannot survive in an extracellular environment have reorganized to the EB form and the cellular chlamydial inclusion has fused with the cell membrane to release new infectious particles of *C. trachomatis*.

In the process of infection and replication *C. trachomatis* appears to disrupt normal cellular function very little and the organism appears to require little from the host cell to support its replicative cycle. *C. trachomatis* does, however, appear to require

host ATP and does not appear to generate its own energy sources in its metabolically active RB state.<sup>17</sup> It evades immune detection by avoiding intracellular processing and remaining intact within endocytic vesicles where it completes its entire lifecycle. It appears too that cells infected with *C. trachomatis* are also resistant to apoptosis though the mechanism involved remains unclear.<sup>18</sup> Despite these observations it is apparent that chlamydial infection can be naturally cleared by some hosts, though reinfection is subsequently possible. In others *C. trachomatis* establishes a persistent infection although the correlates with clearance and persistence are as yet unresolved.<sup>19–23</sup>

## Biovars and Serovars of *C. trachomatis*

*C. trachomatis* has been classified into serovars which are associated with distinct type-specific antigens on the surface of EB and which result in specific clinical syndromes.<sup>24</sup>

*Chlamydia trachomatis* biovar *trachoma*, serovars A, B, and C are associated with hyperendemic or tropical trachoma. This disease is a leading cause of blindness in developing countries and is transmitted by ocular discharge.<sup>25</sup> In contrast, *C. trachomatis* biovar *trachoma* serovars D to K cause genital tract chlamydial infections. These serovars can also affect the eye and are responsible for adult chlamydial conjunctivitis and conjunctivitis in newborn babies. Finally *C. trachomatis* biovar *lymphogranuloma venereum* (LGV) serovars L1–L3 causes a separate group of clinical syndromes.<sup>26</sup> This biovar differs from the squamocolumnar-infecting trachoma biovar in that it causes disease of the genital lymphatic tissue and therefore may present with lymph node masses or a symptomatic proctitis resembling inflammatory bowel disease.

## Epidemiology

Genital *C. trachomatis* remains the most common bacterial STD in the developed world.<sup>27,28</sup> In 2008, there were an estimated 200,959 diagnoses of genital chlamydial infection made across all clinical settings in the UK and more than 1.5 million cases are reported annually in the USA.<sup>29,30</sup>

Overall prevalence figures vary, but a recent study of nearly 15,000 young Americans suggested a prevalence of 4.2% with higher rates in women and the highest in African American women where the prevalence reached 14%.<sup>31</sup> Elsewhere in the world *C. trachomatis* prevalence is also very variable. A study from Paris of women attending private gynecology appointments showed a prevalence of only 0.8% overall with a higher prevalence of 5.2% in younger women (less than 21 years old).<sup>32</sup> A study from Thailand reported 5.7% prevalence in pregnant women and one of the highest prevalence estimates (28.5%) has been found in female sex workers in Dakar.<sup>33,34</sup>

Over the past 10 years, diagnoses have risen steadily in men and women across all age groups but the rise has been most pronounced in women aged less than 25 years and men aged 20–24.<sup>35</sup> Young age is one of the strongest predictors of chlamydial infection with various hypotheses proposed to explain this.<sup>19</sup> Sexual behavior is likely to play a large role, however it has also

been suggested that physiological specifics of the immature cervical mucosa may make it more susceptible to infection.<sup>36</sup> It remains theoretical too that advancing age may afford some degree of immunity to clinical infection following repeated previous exposures.<sup>19</sup> The highest rates of *C. trachomatis* diagnosis in the UK are certainly still seen in 16–19 year old women and 20–24 year old men; however rates are higher in women than men in all age groups.<sup>35</sup> Gender statistics need to be interpreted with some caution however as rising rates of reported chlamydial infection are likely to be at least in part a result of increased screening for the organism using more sensitive tests. In addition, opportunistic screening inevitably happens more frequently in women as they present for cervical smear testing and contraceptive reviews, hence estimates of *C. trachomatis* infection in men may be falsely low. In the United States of America prevalence in 18–26 year old men has been reported as 3.7% with rates highest again in those with African American heritage (11%).<sup>31</sup> A study of nearly 1500 adolescent high school males found a higher overall prevalence of 6.8% for *C. trachomatis* infection and data from the National Health and Nutrition Examination Survey of the USA (1999–2002) suggest that rates of chlamydial infection are higher in black and Hispanic men and those in prison or other correctional institutions.<sup>37,38</sup> Additional studies have confirmed chlamydial infection to be more frequent in ethnic minorities and those incarcerated.<sup>39,40</sup> *Chlamydia trachomatis* prevalence studies in men are often conducted in military settings and allow some limited geographical comparisons. A study from four American military bases suggested a *C. trachomatis* prevalence of 4.1% among male recruits, however higher estimates have been reported from similar patient populations from Scotland (9.8%) and Stockholm (10%).<sup>41–43</sup>

The prevalence of *C. trachomatis* in pregnant women has been reported to vary from 2% to 20% in different study populations, with all studies finding the highest prevalence in younger pregnant women.<sup>44,45</sup> A UK cohort study estimated an overall pregnancy prevalence of 2.4% with a rise to 14.3% in adolescent women and a report from the USA suggested an even higher prevalence in pregnant adolescents (18%).<sup>46,47</sup> This is certainly a source of great concern as it appears that *C. trachomatis* is relatively efficiently transferred from infected mother to neonate during vaginal delivery. The risk for neonatal acquired conjunctivitis is in the region of 15–50% and for neonatal acquired chlamydial pneumonia somewhere between 5% and 30% depending upon the test used for *C. trachomatis* detection.<sup>48–52</sup> Furthermore, it is likely that asymptomatic neonatal transmission from infected mothers is even higher, in the region of 50–70% if nasopharyngeal and serological specimens are both included for analysis.<sup>52</sup> It is true that vaginal delivery poses the greatest risk of neonatal transmission though there are rare case reports of neonatal infection following caesarean section, both with and without prior membrane rupture.<sup>53</sup> Although the efficiency of sexual transmission of *C. trachomatis* from partner to partner is unknown, it is likely to be higher from male to female than in reverse. One estimate derived from contact tracing studies

**Table 40.1:** Estimated New Cases of *Chlamydia trachomatis* Infections (in Millions) Among Adults, 1995 and 1999

Region	1995			1999		
	Male	Female	Total	Male	Female	Total
North America	1.64	2.34	3.99	1.77	2.16	3.93
Western Europe	2.30	3.20	5.50	2.28	2.94	5.22
North Africa & Middle Europe	1.67	1.28	2.95	1.71	1.44	3.15
Eastern Europe & Central Asia	2.15	2.92	5.07	2.72	3.25	5.97
Sub-Saharan Africa	6.96	8.44	15.40	7.65	8.24	15.89
South and Southeast Asia	20.20	20.28	40.48	18.93	23.96	42.89
East Asia & Pacific	2.70	2.63	5.33	2.56	2.74	5.30
Australia & New Zealand	0.12	0.17	0.30	0.14	0.17	0.30
Latin America & Caribbean	5.01	5.12	10.13	4.19	5.12	9.31
Total	42.77	46.38	89.15	41.95	50.03	91.98

confirms infection rates of 65% for female partners of men with chlamydial urethritis.<sup>54</sup>

Chlamydial infection is also common outside the developed world. Globally in 1999 it is estimated that approximately 92 million cases occurred, affecting 52 million women and 40 million men. Statistics gathered and published by the World Health Organization (WHO) shows that rates of infection appear to have fallen over recent years in some regions while rising in others (See Table 40.1).<sup>55</sup>

## C. trachomatis and HIV Transmission

There has been some speculation regarding the role of *C. trachomatis* in enhancing HIV acquisition and a number of prospective cohort studies do suggest an association. A small study from Thailand found an adjusted risk ratio of 3.3 for cervical chlamydial infection and HIV seroconversion and a larger study in Zaire of 430 HIV-negative female sex workers showed an odds ratio for HIV seroconversion among those with chlamydial infection of 3.6.<sup>56,57</sup> It seems scientifically plausible that *C. trachomatis* infection of genital sites could recruit greater numbers of immune and inflammatory cells which would then act as ready targets for any HIV organisms present.

## Pathology

Intracellular inclusion bodies are the hallmark of infection with *C. trachomatis*. They were first described in trachoma in 1907 and subsequently in cells within urethral discharge.<sup>58</sup> Similar findings have been noted in histological sections of cervical mucosa

infected with the organism.<sup>59</sup> Rectal infection with the *trachoma biovar* may correspondingly produce little in the way of visible pathology though there may be the appearance of a nonspecific proctitis with an inflammatory infiltrate.<sup>60</sup> Inclusion bodies are cytoplasmic vacuoles readily seen on light microscopy and when examined in more detail using electron microscopy can be seen to contain many small spherical organisms which are the EB of *C. trachomatis*. Infection with LGV serovars produces a very different pathological picture with a local lymphoproliferative response and the development of true lymphoid follicles within the mucous membranes.<sup>61,62</sup>

The immune response to chlamydial infection is also evident pathologically. In the *trachoma biovar* neutrophil polymorph cells are seen in abundance and there is also an infiltration of macrophages, T and B lymphocytes.<sup>63</sup> It is this inflammatory response that probably results in the scarring of mucous membranes often seen following chlamydial infection. Certainly reinfection with *C. trachomatis* appears to result in more severe disease in primates and humans and is associated with a higher rate of complications.<sup>64,65</sup> It has been postulated that the chlamydial heat shock protein (HSP60) may be the target of the inflammatory response, hypersensitivity to which results in the cellular destruction often seen following infection with this organism.<sup>66,67</sup>

## Clinical Features

A significant proportion of infections with *C. trachomatis* produce no discernible symptoms in the host, thereby facilitating transmission of the pathogen to others.<sup>2,68</sup> This is particularly true in women, where cervical infection is the most common site affected. In such cases women may have an asymptomatic cervicitis (Fig. 40.4a,b), visible only on clinical examination, or may complain of such symptoms as increased vaginal discharge, post-coital/intermenstrual bleeding or lower abdominal pain.<sup>69,70</sup> Clinical signs of chlamydial infection in women also vary accordingly and physical examination may reveal no abnormality of the cervix, or in some cases mucopurulent discharge associated with cervical friability. Women with *C. trachomatis* may also present with symptoms or signs related to urethral infection, namely urinary frequency, dysuria, or suprapubic pain.<sup>71</sup> Urethral swabbing or urinalysis will confirm pyuria but no organisms will be demonstrated on gram stain or culture.

In men, chlamydial infection can also be harbored without symptoms, however, *C. trachomatis* is the most commonly identified cause of NGU and therefore may present with symptoms such as dysuria and/or urethral discharge (Fig. 40.5).<sup>1,72</sup> As in the case of urethral infection in women, urethritis can be confirmed by the presence of leukocytes on a gram-stained urethral smear prior to specific tests to identify *C. trachomatis*. In some patients an erosive or papular, painless rash may be found on the penis in association with chlamydial infection and this is described as circinate balanitis (Fig. 40.5).<sup>73</sup>

**Fig. 40.4:** Chlamydial infection of the cervix: mucopurulent cervicitis (a) before treatment, and (b) 6 weeks after treatment with tetracycline. Courtesy: E Rees: From: Arya OP and Hart CA, eds. Sexually Transmitted Infections and AIDS in the Tropics. CAB International, Wallingford, Oxon, 1998, Plates 98 [a] and [b].

*Chlamydia trachomatis* may infect the rectum in both sexes, although actual symptomatic proctitis is rare with the non-LGV serovars.<sup>74</sup> Occasionally men who have sex with men (MSM) may present with a distal proctitis secondary to *C. trachomatis*, the most common symptoms of which are anorectal pain, rectal discharge, and/or tenesmus.<sup>7,75</sup> Symptomatic proctitis is much more commonly seen with LGV. Chlamydial conjunctivitis can

**Fig. 40.5:** Penile discharge and circinate balanitis in association with urethral *Chlamydia trachomatis* infection.

**Fig. 40.6:** Conjunctivitis caused by *Chlamydia trachomatis*.

also occur in both sexes, most commonly in association with concurrent genital infection (Fig. 40.6).<sup>76</sup>

In an infected neonate the most common clinical presentation is conjunctivitis presenting up to 2 weeks after delivery. The conjunctivitis may be mild to severe ranging from a watery discharge to a blood-stained mucopurulent exudate and although early treatment favors an excellent prognosis, untreated infection can cause scarring.<sup>77,78</sup> Neonates infected during delivery with *C. trachomatis* may less commonly present with pneumonia, evident within 2 to 8 weeks after birth in the majority of cases. This is usually manifested as a cough accompanied by tachypnea with variable hypoxemia and bilateral interstitial infiltrates on a chest radiograph.<sup>79</sup>

LGV has a clinical presentation classically consisting of three phases.<sup>80</sup> The primary lesion appears 3–30 days after infection but is transient and can be missed. It may be a painless papule or pustule or shallow erosion, usually found on the coronal sulcus

in men and on the posterior vaginal wall fourchette or vulva in women. Cervical and extragenital lesions have been reported such as in the oral cavity and extragenital lymph nodes.<sup>81,82</sup>

The secondary stage of LGV is characterized by inflammation and swelling of lymph nodes and surrounding tissue with large necrotic lymph node (bubo) formation. This is usually inguinal or femoral in location, frequently unilateral and may involve a single or many nodes. Nodes may progress to ulceration and discharge pus from multiple points, creating chronic fistulae. The majority of patients with LGV infection recover after the secondary stage without sequelae, but in a few patients progressive spread of *C. trachomatis* incites a chronic inflammatory response including proctitis, acute proctocolitis mimicking Crohn disease, fistulae, strictures, and a chronic granulomatous disfiguring condition of the vulva.

In the recent outbreaks occurring among MSM in Western Europe and the USA almost all cases of LGV presented with proctitis. Symptoms included severe rectal pain, mucous and/or hemorrhagic rectal discharge, tenesmus, constipation, and other signs of lower gastrointestinal inflammation, often severe. In these more recent cases, genital ulcers and inguinal symptoms appear to be rare manifestations of LGV.<sup>83</sup>

## Complications

Untreated *C. trachomatis* infection in women will lead to pelvic inflammatory disease in 10–40% of cases, although a proportion of these will be asymptomatic.<sup>5,84,85</sup> Patients with pelvic inflammatory disease may present with pelvic pain, fever, and systemic upset or dyspareunia, and symptomatic or asymptomatic infections may later present with tubal factor infertility, chronic pelvic pain or ectopic pregnancy.<sup>86,87</sup>

In men *C. trachomatis* infection may lead to epididymo-orchitis with pain, erythema, and swelling of the scrotal contents.<sup>88</sup> In contrast with women, however, chlamydial infection has not been proven to cause infertility in males.<sup>89</sup>

A small percentage of men with urethral chlamydial infection will develop a reactive arthritis and of these, up to a third will manifest the triad known as Reiter syndrome, i.e., arthritis, urethritis, and conjunctivitis.<sup>73,90</sup> Although advances in molecular diagnostic testing for *C. trachomatis* have enabled the identification of chlamydial DNA in synovial tissue in some such cases it is not universally present.<sup>91,92</sup> Similarly, treatment of such patients with longer courses of antibiotics does not appear to alter the likelihood of, or time to, resolution of joint symptoms.<sup>93</sup>

Occasionally *C. trachomatis* infection can cause perihepatitis with inflammation of the liver capsule and this is more common in the context of pelvic inflammatory disease.<sup>94</sup> In such cases, referred to as Fitz-Hugh-Curtis syndrome, the patient will complain of right upper quadrant pain, worse on inspiration although liver enzyme analysis is usually normal. The exact mechanism of the perihepatitis is uncertain and it may result from either direct infection spread through the peritoneum or by immune-mediated means.

Long-term complications of untreated LGV can include lymph node destruction with resulting lymphedema of the genitals (elephantiasis) and persistent suppuration.<sup>80,95</sup>

## Diagnosis

*C. trachomatis* cannot be cultured on artificial media and therefore traditionally tissue culture was used to establish a diagnosis. Recent advances in molecular diagnostic technology however have revolutionized the diagnosis of *C. trachomatis* infection. Although available diagnostic tests for *C. trachomatis* still include culture, enzyme-linked immunosorbent assay (ELISA) and direct immunofluorescence (DIF), the most sensitive and specific tests are now based on nucleic acid amplification techniques (NAATs).<sup>96–98</sup> These include polymerase chain reaction (PCR), transcription mediated amplification (TMA), and strand displacement amplification (SDA) tests, and have the advantage of being able to be performed on urine samples as well as genital swabs.<sup>99</sup> The sensitivities of NAATs in cervical and urethral swabs are more than 95% and although these tests have been validated in urine samples for both men and women more variable sensitivities have been reported using urine in women.<sup>100–103</sup> More recently however, in female patients self-taken vulvovaginal swabs have been demonstrated to have similar sensitivities to a physician-taken cervical swab.<sup>100,104</sup>

When obtaining samples for *C. trachomatis* testing from extra-genital sites (rectal, pharyngeal, and conjunctival), it should be noted that currently no NAATs have licensing approval for these sites. Despite this, in the absence of culture or DIF many clinical centers in the UK and elsewhere are using NAAT tests for samples from these sites with consistently reproducible results.

The one current disadvantage of NAAT based tests for *C. trachomatis* concerns the time taken to receive a test result, usually some days. For this reason some 'point of care' or 'rapid chlamydia tests' have been piloted. These immunoassay-based procedures are based on monoclonal antibody binding to chlamydial antigens from self-taken vaginal swabs and can provide results within 30 minutes of specimen taking with the additional advantage of being cheaper than NAAT tests and uncomplicated to interpret.<sup>105</sup> This type of test has obvious potential uses in resource-limited settings, however sensitivity results to date have been disappointingly variable precluding their more widespread use at present.<sup>106,107</sup>

Serological testing is generally not helpful in the diagnosis of genital tract *C. trachomatis* infection since the presence of antibody may simply be a reflection of past infection with the organism or cross reaction with *Chlamydothila pneumoniae*. Although seroconversion from negative to positive or alternatively a fourfold rise in titer may correlate with the isolation of *C. trachomatis* this is rarely clinically useful as the antibodies may take in excess of 4 weeks to be detectable.<sup>108</sup>

## Treatment

Uncomplicated cases of genital chlamydial infection can be treated using a single 1 g dose of azithromycin given orally. An alternative appropriate treatment is doxycycline 100 mg twice daily orally for 7 days. Both of these antibiotic options have been extensively used and demonstrate a similar high cure rate of >95% at follow-up.<sup>109,110</sup> Second-line treatments for *C. trachomatis* include erythromycin (500 mg twice daily for 10–14 days) and ofloxacin (200 mg twice daily or 400 mg once daily for 7 days). Ofloxacin has comparable efficacy to doxycycline; however, it has been suggested by a number of studies that erythromycin may be less effective, particularly if given for less than 10 days.<sup>110–112</sup>

When infection with *C. trachomatis* is found during pregnancy, a number of treatment options may be considered. Erythromycin 500 mg 4 times daily for 7 days can be given but may be poorly tolerated because of side-effects.<sup>113</sup> There are, however, no trial data to confirm efficacy of the better tolerated regimen of erythromycin 500 mg twice daily for 14 days. Azithromycin 1 g single dose is not currently licensed for use in pregnancy; however, many clinicians are happy to prescribe it, and available data suggest that it is safe to do so.<sup>114</sup> Where erythromycin is not tolerated and there is a wish to avoid azithromycin then amoxicillin 500 mg 3 times daily for 7 days can be used.

Uncomplicated rectal infection with non-LGV chlamydial strains may be treated with azithromycin 1 g orally, however the cure rate may be less than 90%.<sup>115</sup> LGV infection is more invasive and therefore requires a longer period of systemic treatment for eradication. In confirmed cases it is suggested to give 21 days of doxycycline at a dose of 100 mg twice a day or an alternative regimen is 21 days of erythromycin 500 mg 4 times daily.<sup>116</sup>

## Vaccines

Although several *C. trachomatis* antigens have been suggested as potential vaccine candidates, attempts to produce a prophylactic vaccine have not been successful to date.

Early attempts in the 1960–70s used whole, killed *C. trachomatis* and initially short-term protection seemed to be produced in experimentally infected blind volunteers. Subsequently however, vaccination appeared to enhance the severity of ocular disease in individuals reinfected with the organism hence such efforts were abandoned.<sup>117</sup>

The ability of *C. trachomatis* to cause repeated infections in the same host suggests that a vaccine induced immune response would need to be greater than the natural immune response in the host. In addition the situation is complicated by the fact that correlates of natural immunity to *C. trachomatis* in humans are not yet fully understood.<sup>118</sup> Animal studies and observational cohort studies in humans with human immunodeficiency virus (HIV) infection suggest that CD4+ T-lymphocytes may play an important role, particularly those which are T-helper Type 1 MOMP-specific,

however the role of the CD8+ T-cell appears less clear.<sup>119–123</sup> This is thought to be in part a result of the intracellular, membrane-protected lifecycle of the *C. trachomatis* organism which largely prevents its degradation and presentation to CD8+ cells. Despite this, antigen-specific CD8+ cytotoxic T-cell responses have been demonstrated in the setting of chlamydial infection.<sup>124,125</sup> The role of antibodies in immunity to *C. trachomatis* infection seems similarly complex. Although serum antibody titers do not correlate with protection it appears that local IgA mucosal protection may play a more important role.<sup>126–129</sup>

Vaccine studies to date suggest that a successful candidate vaccine would need to induce CD4+ T-Helper Type 1 responses (via interferon-gamma) and also a humoral response to be effective. Recent efforts have been focused on recombinant MOMP vaccines which avoid the potential safety concerns which can be associated with live attenuated or killed, whole-organism products.<sup>130</sup> Recombinant MOMP it seems, however, is not easy to produce, particularly on a large enough scale for commercial vaccination purposes. Research groups therefore continue to investigate novel protective antigens and delivery systems which will hopefully yield more promising and durable results.<sup>119,131–134</sup> In particular *C. trachomatis* DNA vaccines appear to be promising candidates and are undergoing analysis by several major vaccine companies.<sup>135–138</sup>

## Prevention

Prevention of sexually transmitted infections such as *C. trachomatis* necessitate a multi-faceted approach including public education, the treatment of known infected individuals, the screening and treatment of their contacts, and screening of asymptomatic individuals who may carry the organism and be capable of transmitting it.<sup>139</sup>

The prevalence of asymptomatic untreated chlamydial infection is high as illustrated in cross-sectional studies from the UK which suggest estimates of 10–13% and are likely to be even higher in the developing world.<sup>140</sup> Screening of those who may be asymptotically infected ideally needs to be targeted towards those at risk and a number of risk factors for chlamydial infection have been identified to date. These include age (adolescents and young adults), recent change in sexual partner, a high number of lifetime sexual partners, non-use of barrier contraceptives, a history of previous sexually transmitted disease, and lower educational or socioeconomic status.<sup>140–145</sup> In addition, screening requires a minimally-invasive, sensitive, and specific test which is applicable across large population groups. Again the advances in NAAT testing for detection of *C. trachomatis* have facilitated the development of potential screening programs, though their relatively high cost may preclude their widespread use in resource-poor settings.<sup>96,146</sup> Finally, the relative ease with which *C. trachomatis* can be treated also contributes to its consideration as a target of a

primary prevention screening program, as does the potential likelihood of complications from untreated infection. In a randomized controlled trial screening women at risk of chlamydial infection was associated with a reduced rate of pelvic inflammatory disease.<sup>147</sup>

Sweden was the first country to commence a screening program for asymptomatic chlamydial infection which began in 1982.<sup>148</sup> This opportunistic approach targeted women less than 30 years of age who presented seeking contraception, termination of pregnancy, or antenatal care. Initially rates of *C. trachomatis* fell in the 1990s and this was cited as evidence of success of the screening program. However, it should be noted that decreases in the rate of chlamydial infection in Sweden also corresponded with the national HIV awareness campaign and paralleled decreases in other countries where a *C. trachomatis* screening program was not in operation.<sup>149</sup> In keeping with this, rates of *C. trachomatis* infection in Sweden have risen again since 1995 thus effectiveness of the screening program has yet to be conclusively proven.<sup>150,151</sup> In the USA the Centres for Disease Control (CDC) have supported chlamydial screening since 1988 asserting that all pregnant women be screened at the first antenatal visit with repeated testing in the third trimester in those who are 24 years or younger, or at increased risk in order to reduce neonatal chlamydial infection.<sup>152</sup> In addition the CDC recommends the annual screening of all sexually active women under 26 years of age or those with risk factors for chlamydial infection. In the USA it has been decided that there is insufficient evidence to recommend routine screening of all men but targeted male populations such as those attending sexually transmitted infection clinics and those in prison should be screened for *C. trachomatis*. As in Sweden, chlamydia screening in the USA is voluntary; hence overall adherence to the USA recommendations appears to be poor with uptake of screening by only 26–38% of potentially eligible women.<sup>153</sup>

In the UK the National Chlamydia Screening Programme (NCSP) has been established in England, offering opportunistic *C. trachomatis* screening to all sexually active men and women less than 25 years old in a variety of healthcare and educational settings.<sup>140,154</sup> This program has unfortunately suffered from the same problems as the USA, with poor uptake in many areas despite a co-ordinated and extensively funded national approach. In 2008–2009, when the national rollout of the program was completed, the target for *C. trachomatis* testing among 15–24 year olds was set at 17%. The figure reached was only 15.9%, and with the 2009/10 target raised to 25% it seems unlikely that this will be achieved.<sup>155</sup>

Theoretically *C. trachomatis* remains a candidate for screening programs though there appears to be a lack of evidence of effectiveness of such programs at present. The mode and frequency of screening, as well as the target populations and cost-benefit ratios in areas with varying prevalence of infection are all still subjects of much debate.

## Summary

*Chlamydia trachomatis* is the most common bacterial sexually transmitted infection in the world today with in excess of 90 million cases reported annually worldwide. Infection is commonest in younger men and women and is also associated with a high number of sexual partners and low educational/socioeconomic status. It exists as an obligate intracellular bacterium with two distinct forms—the elementary body (which is the infectious form) and the reticulate body (which is the metabolically active form). *C. trachomatis* is classified into several distinct serovars that are responsible for specific clinical syndromes including tropical trachoma (*C. trachomatis* biovar *trachoma* serovars A-C), genital tract infections (*C. trachomatis* biovar *trachoma* serovars D-K), and proctitis/lymphadenitis (*C. trachomatis* biovar *lymphogranuloma venereum* [LGV] serovars L1-L3).

A significant number of infections with *C. trachomatis* produce no symptoms in the host. Alternatively women may present with pelvic pain, irregular vaginal bleeding or discharge, and men with symptoms of urethritis, namely dysuria and urethral discharge. Chlamydial proctitis may also be asymptomatic, although LGV infection tends to produce rectal pain, discharge or bleeding in the host. Complications of *C. trachomatis* infections include pelvic inflammatory disease, epididymo-orchitis, Reiter syndrome, and female infertility. In current times, *C. trachomatis* is most frequently diagnosed using nucleic acid amplification tests (NAATs), although tissue culture can still be used. NAATs are not currently licensed for use on samples from extra-genital sites, but are widely used with good clinical reproducibility.

Treatment of uncomplicated *C. trachomatis* infection can be in the form of a single 1 g oral dose of azithromycin or a week's course (100 mg twice a day) of doxycycline, both of which have a cure rate of >95%. Erythromycin can be used in pregnancy or in the penicillin-sensitive patient. LGV requires a longer treatment course of doxycycline (100 mg twice a day for 21 days).

Globally, several screening programs exist for the detection of *C. trachomatis* in patients thought to be at risk including those in Sweden, USA, and the UK. In all cases, screening is opportunistic, mainly directed at women and suffers from less than ideal uptake. Although there have been several proposed *C. trachomatis* antigens as vaccine candidates, none have been successful to date and work continues in this area.

# Lymphogranuloma Venereum

Henry JC de Vries • Bellum Shiva Nagi Reddy  
• Sujay Khandpur

41

## Introduction

Lymphogranuloma venereum (LGV) is a sexually transmitted chlamydial disease that primarily involves the lymphatics. Many synonyms have been used in the past for this condition, such as tropical bubo, climatic bubo, paradenitis inguinalis, Durand–Nicolas–Favre disease, lymphopathia venereum, and the fourth, fifth or sixth diseases. However, the name LGV is prevalent because it clearly differentiates it from another sexually transmitted disease, granuloma inguinale. The disease is universal in occurrence with a large number of cases seen in the tropical parts of Africa, Asia, and South America. Since 2003 it is endemic among men who have sex with men (MSM) with high risk sexual behavior, especially in Europe but it is also found in North America and Oceania. Recently several endemically transmitted heterosexual cases of LGV have been reported from Spain and Portugal. The etiologic agent is *Chlamydia trachomatis* biovars L-1, 2, 3. The nomenclature to identify different *C. trachomatis* strains depends on the diagnostic method used. For antibody based techniques the term serovar is used, and for nucleic acid based tests the term biovar. For the sake of clarity the more general term biovar is used throughout this chapter.

## History

LGV is an ancient disease, known since the 18th century, and the historical aspects of this disease have been extensively reviewed in the monographs by Stannus, Kampmeier et al., Koteen, Favre and, Hellerstrom, and Rajam and Rangiah. Though the initial description of LGV was attributed to Wallace (1833),<sup>1</sup> the venereal nature of this condition was pointed out by Nelaton (1890) and his pupil, L'Hardy (1894). In India, Caddy was the first to describe this condition in 1902 under the name “climatic bubo.” LGV was often confused with the lymphadenopathy of other diseases, such as tuberculosis, syphilis, and chancroid. Durand, Nicolas and Favre for the first time established it as a distinct clinico-pathologic entity in 1913 under the name “lymphogranuloma inguinale” In 1922, Phylactos suggested a common etiology of climatic bubo and LGV.

One of the significant milestones in the diagnosis of LGV was the development of an intradermal test by Frei in 1925 by using aspirated pus from the unruptured bubo as antigen. Viral etiology of this condition was suspected by Hellerstrom et al.<sup>2</sup> The organism was isolated successfully by Favre et al. in 1930 after intracerebral inoculation of monkeys with the aspirate obtained from buboes.<sup>3</sup> In 1935, Miyagawa succeeded in growing the LGV related *Chlamydia* in embryonated hen's eggs and made possible the production of large amounts of antigen for the Frei test and other serodiagnostic investigations. A complement fixation test was developed in 1930.<sup>4</sup> Sheldon and Heyman in 1947 described the histopathologic features of LGV by observing the pathognomic “stellate abscesses” in the affected lymph nodes.<sup>5</sup> Recent developments in the diagnosis of LGV include the introduction of biovar specific nucleic acid amplification tests (NAATs) which are generally considered the gold standard in LGV diagnostics.<sup>6,7</sup> Older techniques which are used less frequently today are the micro-immunofluorescent test by Wang et al.,<sup>8</sup> introduced in 1975, culture of the organism and other cytologic methods of detection.<sup>9,10</sup>

## Epidemiology

LGV was formerly known as a sexually transmitted infection confined to equatorial regions but also as an “imported” sexually transmissible infection in the Western world. However since 2003, with the first cases of LGV proctitis among MSM reported in the Netherlands, an ongoing epidemic has been revealed in Western society dating back to at least 1981.<sup>11–14</sup>

In the beginning of this MSM associated LGV epidemic the great majority of cases were caused by biovar L2b, also known as the Amsterdam variant, and confined to a “core group” of HIV positive individuals with multiple co-infections like hepatitis C, engaging in high risk sexual behavior like unprotected anal intercourse, multiple anonymous partners, group sex, and use of anal enemas.<sup>15–17</sup> Recently there are reports from Spain and Portugal of heterosexual spread of LGV infections caused by the L2 biovar, but not the specific L2b biovar which causes most LGV infections among MSM in

Europe.<sup>18,19</sup> Nonetheless, it is feasible that the MSM LGV epidemic has spread from the initial “core group” via a bridging population to the community at large. An excellent review of the recent LGV epidemic among MSM has been written by White.<sup>20</sup>

Until 1990s, LGV was endemic in several tropical and subtropical countries including West, Central and East Africa, India, Malaysia, Korea, Vietnam, South America, Papua New Guinea, and the Caribbean Islands.<sup>21–26</sup> Perhaps, the lack of specific diagnostic criteria in these studies and the relatively poor degree of clinical suspicion of this condition may have biased these estimates. Two cross-sectional surveys undertaken in STD clinics in Jamaica in 1982–83 and 1990–91 revealed disease prevalence of 4.1% and 3.9%, respectively. In 1996, the prevalence decreased to 2.63%.<sup>27</sup> An epidemic of LGV has been reported from the Bahamas and it was attributed to epidemics of crack cocaine use and HIV infection.<sup>28</sup> In Madagascar in 1997, 8% of genital ulcer disease patients were clinically diagnosed as LGV with only 0.5% accounting for confirmed cases by micro-IF test.<sup>29</sup> In Hong Kong, the disease accounted for only 0.001% of all the new STD cases in 1995.<sup>30</sup> A prevalence of 1% was recorded in STD clinics in Singapore in 1995.<sup>31</sup> In Nairobi, Kenya, 0.6% of genital ulcer disease was attributed to LGV in 1996.<sup>21</sup> In South Africa, LGV was seen in 3.2–11% of patients with genital ulcer disease.<sup>32,33</sup> In Nigeria, LGV was the most common cause of genital ulcers in women attending STD clinics.<sup>34</sup> A prospective study of inguinal buboes conducted in Thai men between 1987 and 1989 revealed LGV-*C. trachomatis* by immunofluorescent microscopy in 3.9% of the cases.<sup>25</sup>

However, late reports suggest that the disease has declined considerably in tropics and only sporadic cases are reported. In an STD clinic in New Delhi, India, LGV comprised of 3.4% of all STD cases (5.7% in males and 0.3% in females) during 1990–1993, in comparison to only 0.2% during 2002–2004 (0.4% in males and 0% in females).<sup>35</sup>

LGV has been reported to occur more frequently in men than in women. It probably remains underdiagnosed because of the asymptomatic nature of the early lesions in women.<sup>36</sup> However, in a more recent study performed in Durban, South Africa, among 520 consecutive consenting patients presenting with genito-ulcerative disease between October 2000 and April 2001, the prevalence of LGV in women was 19% versus 10% in men ( $P = 0.006$ ).<sup>37</sup> Late complications, such as ulceration, rectal strictures, or esthiomene, are more frequently reported in women. The disease has a peak incidence during the second and third decades of life which corresponds with the peak age of sexual activity. It is more common in urban populations, among MSM in Western society, among the sexually promiscuous and lower socio-economic classes. To date, the specific LGV epidemic among MSM presenting with acute proctitis has not been identified other than in Western countries.<sup>38</sup> Commercial sex workers play a major role in disease transmission, as was documented during an outbreak in Florida in the late 1980s.

Sexual intercourse is the most common mode of disease transmission. Primary LGV lesions of the mouth and pharynx

occur as a result of receptive oral sex.<sup>39</sup> However, non-venereal transmission to healthcare personnel from ruptured buboes and other infected tissues has also been reported. There are reports of laboratory acquired infection following inhalation of highly concentrated virulent culture material.<sup>40</sup> Transplacental transmission has not been documented, although the infection may be acquired through an infected birth canal.<sup>41</sup>

## Biology

LGV is caused by *Chlamydia trachomatis* biovars L1, L2, and L3, of which L2 is the most common serotype. By the end of the last century, the rarer L1 biovar had been identified in MSM with proctitis.<sup>42</sup> In the recent epidemic among MSM a new variant L2b (also known as the Amsterdam variant) has been identified which has been circulating unnoticed for decades in the United States and Europe until the outbreak was unveiled in 2004.<sup>43</sup> The clinical manifestations of this strain are less severe than the L2 biovar.

Chlamydiae are a group of intracellular microorganisms causing pneumonia, psittacosis, trachoma and LGV in humans, and diverse diseases in many avian and mammalian species. They are filterable organisms, do not grow in cell free media, possess a cell wall, multiply by binary fission, contain both DNA and RNA and are obligate anaerobes that do not contain a cytochrome system or produce ATP.<sup>44</sup> This genus is classified into two species. *Chlamydia psittaci*, a common pathogen of avian and mammalian species, forms diffuse vacuolated inclusions without a glycogen matrix and is resistant to sulfonamides. *Chlamydia trachomatis*, a natural human parasite, causes infection of the eye and genitalia. It forms compact inclusion bodies, contains glycogen matrix and is sensitive to sulfonamides.<sup>45</sup> *Chlamydia trachomatis* contains three biovars, that is, murine, LGV, and trachoma biovars.<sup>46</sup> They are classified into 15 biovars on the basis of neutralization and immunofluorescent tests, of which A, B, Ba, and C cause endemic trachoma, types D to K cause oculo-genital infection, and biovars L1, L2 and L3 are responsible for LGV. There is almost complete DNA homology between LGV and trachoma biovars. They are also related serologically but differ in the type of cells they invade. The trachoma biovar infects only squamo-columnar cells, whereas LGV strains are more invasive and penetrate and replicate within macrophages. They are lymphotropic organisms that cause thrombolympangitis and perilymphangitis.<sup>47</sup> Recently, Thomson et al. completed the genomic analysis of the remaining *C. trachomatis* biovariant, LGV.<sup>48</sup> They found that the LGV genome is remarkably similar to the previously sequenced ocular and genital *C. trachomatis* isolates. This rules out the possibility that additional acquired DNA present in *C. trachomatis* strain L2 could explain differences in tissue tropism and disease outcome. Gene loss and/or small-scale mutational change are the major driving forces determining host adaptation and tissue tropism of different biovars of *C. trachomatis*.

Trachoma and LGV biovars differ in their heparin-inhibitable interaction with mammalian cells. Serovar L1 is significantly

more dependent on a heparan sulfate-related mechanism of infectivity than is serovar E. In LGV biovars a 60 kDa OmcB protein has been reported to bind heparan sulfate.<sup>49</sup> It is thought that OmcB might be responsible for the differences in the clinical presentations of trachoma biovars and LGV biovars.<sup>50</sup>

## MORPHOLOGY

Chlamydiae are complex microorganisms that were earlier considered to occupy a position intermediate between bacteria and viruses. Following the suggestion of Moulder, they are considered as small bacteria adapted to obligate intracellular parasitism.<sup>51</sup> The LGV-*Chlamydia* elementary body (EB) consists of an outer cell wall, which is made up of geometrically arranged, 20 nm diameter subunits, that lack the muramic acid and peptidoglycan moiety.<sup>52</sup> The cell wall possesses two types of antigen; a common heat stable, complement fixing antigen that can be extracted in either deoxycholate, chloroform or methanol, and a type specific, heat-labile antigen, which is extractable with trypsin or deoxycholate and helps differentiate the different biovars by complement fixation or neutralization tests. It produces an endotoxin like factor, which is responsible for constitutional symptoms of fever, chills, and fatigue that precede the onset of inguinal LGV. Like all Gram negative bacteria, lipopolysaccharide is a surface component of *C. trachomatis*.

Inner to the cell wall is the trilaminar outer membrane that contains a 38–43 kDa, cysteine-rich major outer membrane protein (MOMP).<sup>53</sup> This protein shows disulfide linkage and maintains the structural and functional integrity of the outer membrane. A reduction in disulfide linkage occurs when the elementary body (EB) changes to reticulate body (RB). MOMP is a porin that plays an important role in the attachment of EBs to host cells. Nine polymorphic MOMP genes (pmp A to pmp H) have been identified in the genome of biovar L2.<sup>54</sup> The L1 biovar MOMP contains 371 amino acids while L2 contains 372 amino acids. Other proteins that are detected in the outer membrane include polymorphic OMPs E, G, and H, a mixture of 46 kDa proteins, modified forms of MOMP, penicillin binding proteins and Mip-like protein.<sup>55</sup> The Mip-like protein is a 27 kDa protein with homology of the 175-amino acid C-terminal fragment to the surface exposed *Legionella pneumophila* Mip-gene product.

Inner to the outer membrane is the inner membrane and periplasmic space. The organism possesses both DNA and RNA. However, there is no detectable thymidine kinase and DNA synthesis occurs via the uridine and thymidylate synthetase pathway.<sup>56</sup> There is also present a 4.4 MDa plasmid and the genome contains 16S RNA genes.<sup>57,58</sup>

Several mechanisms by which *Chlamydia trachomatis* attaches to and infects host cells have been described. Proposed ligands include the major outer-membrane protein (MOMP), heat-shock protein 70 and glycosaminoglycans. A cryptic 7.5 kb plasmid of unknown function is maintained by human Chlamydial strains. This is associated with accumulation of glycogen, while the plasmid-less isolates fail to do so. Carlson et al. demonstrated in

LGV biovars that the plasmid's biological effect on chlamydial pathogenesis is associated with *in vivo* infection, which enhances the pathogen's ability to colonize and sustain infection in the mouse female genital tract.<sup>59</sup> Fedel and Eley's work suggests that *C. trachomatis* lipopolysaccharide plays a role in infectivity towards epithelial cells. They demonstrated that *C. trachomatis* LPS and *C. trachomatis* LPS antibody significantly reduced infectivity, mostly in a dose-dependent manner. However, with all the LPS inhibitors used, there was greater inhibition against biovar E than biovar LGV1.<sup>60</sup>

## STAINING PROPERTIES

The EB is gram-negative but stains readily with Giemsa, Castaneda, Machiavello, or Gimenez stains. It stains faint blue with hematoxylin and eosin, and black with Warthin–Starry silver impregnation stain. The RB is basophilic and can be stained with Lugol's iodine due to the presence of glycogen matrix. The organism is Periodic acid-Schiff (PAS) negative and not acid-fast.<sup>61</sup>

## RESISTANCE

The organism is heat-labile, being inactivated within minutes at 56°C. It is susceptible to ethanol, ether, and low concentration of phenol and formalin. Infectivity is maintained for several days at 4°C and indefinitely at -70°C.<sup>62</sup>

## GROWTH PROPERTIES

LGV-*Chlamydia* can be propagated in the yolk sac of developing chick embryos, HeLa cells, mouse, and tissue cultures.<sup>63</sup> It forms plaques in cell culture. Unlike the trachoma biovar, infectivity of the host cells is not enhanced by centrifugation or pretreatment with DEAE dextran.<sup>64</sup> Addition of exogenous heparin or heparin sulfate *in vitro* inhibits the infectivity and attachment of the LGV biovar to host cells suggesting that it uses predominantly a heparin-inhibitable mechanism.<sup>65</sup> Growth can be regulated by the addition of essential amino acids derived from either the host cell nutrient pool or from degradation of host proteins. Cysteine is a major amino acid in the OMP and is essential for the differentiation of EB from RB.<sup>66</sup> Cyclic-AMP inhibits chlamydial growth by inhibiting this transformation.<sup>67</sup> Estradiol enhances the growth by lowering cAMP levels.<sup>68</sup>

## Pathology

The causative agent of LGV is a lymphotropic organism that initiates the disease process by causing thrombolympangitis and perilympangitis.<sup>41</sup> After inoculation through abraded skin or mucous membrane, the organisms become concentrated in draining lymph nodes and produce lymphangitis and lymphadenitis. They stimulate endothelial cell proliferation in the lymphatic vessels and lymph channels within lymph nodes. The regional lymph nodes enlarge and undergo necrosis. This is followed by neutrophilic chemotaxis

leading to formation of triangular or quadrangular “stellate” abscesses that become surrounded by epithelioid cells, macrophages and giant cells. These abscesses coalesce to form a multiloculated abscess, which ruptures spontaneously resulting in fistulae and sinus tracts. The inflammatory process subsides with fibrosis, which obstructs the subcutaneous and submucous lymphatic channels resulting in lymphedema, brawny induration of the affected part, and elephantiasis. The regional blood supply is compromised secondarily, which causes ischemic necrosis and ulceration of the overlying skin and mucous membrane. This sequence of events is responsible for “esthiomene” formation of the external genitalia, rectal strictures and ulceration. The anorectal syndrome is an inevitable sequelae in both the sexes when the perirectal glands are involved either by direct or retrograde extension of the infection. Hematogenous spread of the organisms results in systemic infection. Persistence of LGV in the tissues or repeated infection by the same or related biovars may also be important in developing systemic disease.<sup>69</sup> The tissue damage in LGV is caused by a cell-mediated hypersensitivity response to chlamydial antigens.<sup>70</sup> Both cell-mediated and humoral immune responses are observed within 1–2 weeks of infection and correspond to the appearance of chlamydial cytoplasmic inclusions within the tissue phagocytes. The host immunity inhibits chlamydial multiplication, but may not eliminate the organism, resulting in a state of latency.<sup>47</sup>

## Clinical Features

The clinical presentation varies according to the sex of the patient, mode of sexual contact (vaginal or anal sex), and the stage of the disease. LGV is a chronic and progressively destructive disease. The clinical features, grouped conventionally into different stages, comprise of a primary stage, secondary stage (inguinal syndrome), and tertiary stage (genito-anorectal syndrome) (Table 41.1). Apart from these symptomatic stages, there are indications that in MSM LGV disease can remain asymptomatic.<sup>15,16</sup> Since the overall majority of these cases were HIV positive, compromised immunity could have caused the absence of symptoms. The frequency of asymptomatic LGV cases is debated.<sup>71</sup>

### PRIMARY STAGE

The average incubation period is 7–12 days, but may be as long as six months. The primary lesion may be an asymptomatic transient papule, pustule, herpetiform ulcer, or nodular ulceration (Fig. 41.1). Non-specific urethritis with thin, muco-purulent discharge is observed in 5% of males and 15% of females, and balanitis and balanoposthitis are reported in 2% of males.<sup>36</sup> The primary lesion occurs usually over the coronal sulcus, followed by frenulum, prepuce, penile shaft, urethra, glans penis, and scrotum in men and on the posterior vaginal wall, fourchette, posterior lip of the cervix, or the vulva in women. Cervicitis may also be a common manifestation of primary LGV.<sup>72</sup> The infection may extend proximally producing parametritis, endometritis, or salpingitis. In MSM, primary rectal inoculation produces bloody anal discharge, diarrhea and cramps.<sup>1</sup> Primary lesions of the

**Table 41.1:** Clinical Spectrum of LGV

Manifestations	Complications
<b>Primary stage</b> Transient papule, pustule, herpetiform ulcer, nodular ulceration, non-specific urethritis, balanitis, balanoposthitis, bubonulcus, cervicitis, salpingitis, parametritis	Phimosis, labial edema, infertility
<b>Secondary stage</b> (inguinal syndrome) Severe proctitis, bubo formation, inguinal multilocular abscess, Groove sign of Greenblatt	Sinus tracts, frozen pelvis, infertility, systemic arthritis, pneumonia, hepatitis, perihepatitis, meningoencephalitis, endocarditis, spondylitis, ocular inflammatory disease
<b>Tertiary stage</b> (genito-anorectal syndrome) Genital syndrome, anorectal syndrome, proctitis, proctocolitis	Genital elephantiasis, ramrod or saxophone penis, esthiomene, vaginal stenosis, urethral strictures, fistulae (recto-vaginal, urethro-vaginal, vulval), rectal strictures, stenosis, abscess formation (perirectal, ischioanal, suprapubic), rectal adenocarcinoma, lymphorrhoids
<b>Urethro-genito-perineal syndrome</b>	Papillary genital growths, perineal sinus
<b>Ocular manifestations</b>	Mixed papillary-follicular conjunctivitis, episcleritis, corneal ulcers, iritis, iridocyclitis
<b>Cutaneous manifestations</b>	Id eruption—transient generalized exanthemata, papules, pustules, nodules, urticaria, scarlatiniform eruption, erythema multiforme, erythema annulare centrifugum, erythema nodosum, photoallergic dermatitis
<b>Others</b>	LGV tonsillitis, pharyngitis, cholecystitis

**Fig. 41.1:** Primary lesion of lymphogranuloma venereum.

mouth, pharynx or tonsils can result from oral sexual exposure and typically heal within a period of one week without scar formation.<sup>28,73</sup> The primary stage lesion occurs in only 30% of heterosexual men and less often in women, although associated local edema may produce phimosis or swelling of the labia.<sup>1</sup> Rajam and Rangiah did not observe any primary lesion in 68.7% of the male and 58% of female LGV patients. In a study by Scieux et al.,<sup>74</sup> only five of the 27 LGV cases (18.5%) were able to recall having a primary lesion.

In this stage, a cord-like lymphangitis of the dorsal penis may develop, also known as sclerosing lymphangitis. This progresses to form a solitary, large, tender lymphoid nodule or “bubonulus” that may rupture to form sinuses or fistulae.<sup>75</sup>

## SECONDARY STAGE (INGUINAL SYNDROME)

The second stage begins within 2–6 weeks after the onset of primary lesion, but may be delayed for as long as 4–6 months. It is characterized by enlarged and tender regional lymphadenopathy or “Bubo.” The location of lymph node involvement is directly related to the site of the primary lesion (Table 41.2). Lymphadenitis of the submaxillary and cervical glands occurs if the site of primary inoculation is the mouth during receptive oral sex. Inguinal lymphadenopathy occurs if the primary lesion involves the anterior vulva, penis, anterior urethra or anus. Perirectal and deep iliac lymph nodes are enlarged in females if the primary lesion occurs on the posterior vulva, vagina, cervix, or rectum. Seventy five percent of all cases have simultaneous involvement of the deep iliac group of lymph nodes. In one-third of the patients, especially in heterosexual men but also in MSM in the current LGV epidemic in Western society, enlargement of the inguinal lymph nodes above, and the femoral lymph nodes below Poupart’s (inguinal) ligament occurs, resulting in the characteristic “Groove sign of Greenblatt” (Fig. 41.2).<sup>30,76</sup> The inguinal bubo is unilateral in two-third of the cases.<sup>30</sup> As it enlarges, the patient experiences severe pain in the groin and difficulty in walking. In 1–2 weeks, periadenitis sets in and the glands become matted, fixed and adherent to the overlying skin. The lymph nodes undergo necrosis and coalesce to form a multilocular abscess with edema and erythema of the overlying skin. Impending rupture is characterized by livid color (‘blue balls’) of the overlying skin. One-third of the abscesses rupture to form multiple sinus tracts discharging thick, tenacious, yellowish pus for weeks to months. Healing occurs leaving behind contracted scars in the inguinal region. Two thirds of the buboes involute spontaneously.

**Table 41.2:** Lymphatic Involvement Based on Site of Primary Infection

Site of primary lesion	Group of lymph nodes involved
Penis, anterior urethra, anterior vulva, anus	Superficial and deep inguinal
Posterior urethra, rectum, vagina, cervix	Deep iliac, perirectal
Mouth, pharynx	Deep iliac, perirectal, retrocrural, lumbosacral
Hands	Submaxillary, cervical
	Axillary

**Fig. 41.2:** Groove sign of Greenblatt.

Bubonic relapse occurs in about 20% of untreated cases. Inguinal lymphadenopathy occurs in only 20–30% of women with LGV. Primary involvement of the deep iliac or perirectal lymph nodes is more common in women. This involvement may produce symptoms of lower abdominal or back pain, often mistaken for acute appendicitis or tubo-ovarian abscess. When pelvic lymph nodes are involved, cystitis and urinary retention may occur. Perilymphangitis leads to formation of adhesions with the surrounding pelvic organs resulting in “frozen-pelvis.”<sup>30</sup> In the second stage, patients develop constitutional symptoms such as low-grade fever, chills, malaise, myalgia, and arthralgia. Systemic spread results in arthritis, pneumonitis, hepatitis, perihepatitis, meningoencephalitis, endocarditis, spondylitis, and ocular inflammatory disease. Cutaneous involvement in the form of erythema nodosum, erythema multiforme, or erythema annulare centrifugum may also occur.<sup>77</sup>

## SECONDARY STAGE (LGV PROCTITIS)

LGV proctitis, as occurs often in MSM, is characterized by perianal ulcers (Fig. 41.3) severe symptoms like anal cramps,

**Fig. 41.3:** Perianal ulcers of lymphogranuloma venereum proctitis.

**Fig. 41.4:** Proctitis due to lymphogranuloma venereum.

tenesmus, pain, bloody discharge, and constipation occur due to edema of the mucosal lining (Fig. 41.4) and underlying tissue. Normally LGV proctitis is not accompanied by lymphadenopathy noticeable upon physical examination. However, on radiologic imaging, lymphadenopathy in the pelvic area can be identified. In the present LGV epidemic among MSM, a considerable number of the patients with LGV proctitis are asymptomatic at the time of diagnosis, possibly due to the HIV co-infection which accompanies most infections.

### TERTIARY STAGE (GENITO-ANORECTAL SYNDROME)

This stage develops in 25% of untreated patients, predominantly in women who remain asymptomatic in the previous two stages, or in MSM who engage in receptive anal intercourse. In heterosexual men, it may occur by lymphatic spread from the posterior urethra. In women, the rectal mucosa may be directly inoculated during anal intercourse, by contamination with infectious vaginal secretions, or by lymphatic spread from the cervix and posterior vaginal wall. The persistence of infection in the anogenital tissue provokes a chronic inflammatory response causing procto-colitis, perirectal abscesses, fistulae, strictures and rectal stenosis, as well as hyperplasia of the intestinal and perirectal lymphatics leading to “lymphorrhoids.”<sup>78</sup>

### Genital Syndrome

Hyperplastic ulcerative changes may occur in the genitalia of both sexes, more commonly in women.<sup>79</sup> In men, chronic bilateral inguinal lymphadenitis leads to penile and scrotal elephantiasis, approximately 1–20 years after infection. It may affect only the prepuce, penile shaft, scrotum, or the entire external genitalia. The genital tissue becomes indurated and deformed. The penis becomes solidified giving rise to “ramrod penis.” It may sometimes be twisted resembling a saxophone (Fig. 41.5).<sup>80</sup>

Vascular compromise results in large destructive ulcers or occasionally superficial ulcers with irregular, serrated edges.

In women, chronic progressive lymphangitis and inguinal and pelvic adenitis leads to chronic edema, sclerosing fibrosis of the

**Fig. 41.5:** LGV in a man—saxophone penis.

subcutaneous tissue, elephantiasis, and chronic genital ulceration, referred to as *esthiomene* (Greek; ‘eating away’). It involves the labia, vulva, and clitoris, which gradually become enlarged. The size may vary from mere tumefaction of the lips to large, pendulous, multilobulated, unsightly masses of hypertrophied tissue hanging down and obstructing the vulval cleft (Fig. 41.6). The external surface of the labia majora, genito-crural folds, fourchette, urethral orifice, root of the clitoris, and perineum develop ulceration. These ulcers may be localized, large and superficial, or perforating. Rarely, penoscrotal elephantiasis due to LGV can occur in men also.<sup>79</sup> Genital sclerosis and ulceration result in serious sequelae. In women, it leads to vaginal stenosis, urethral strictures, and recto-vaginal, urethro-vaginal, vulval, or urinary fistulae. In a retrospective study conducted in Nigeria, LGV was found to be responsible for 0.55% of urinary fistulae in women.<sup>81</sup> In men, the complications include urethral strictures, prostatitis, seminal vesiculitis, and epididymo-orchitis.<sup>30</sup>

### Anorectal Syndrome

Chronic inflammation of the pelvic, perirectal and anorectal tissues leads to hyperplastic ulcerative changes in the anorectal mucosa. The infection is usually confined to the lower 8–10 cm of the anorectal region especially the portion below the peritoneal reflection, but may occasionally spread to the bowel as far as the transverse colon.<sup>78</sup> The condition begins as localized or diffuse edema of the anorectal mucosa causing pruritus and rectal discharge. On per rectal examination, localized or diffuse

**Fig. 41.6:** LGV in a woman—esthiomene originating from clitoris. Courtesy: Dr. Usha Gupta, Jabalpur, India and Dr. Somesh Gupta, Chandigarh, India.

pebbled appearance of the mucosa is felt due to enlarged and infected anorectal and pararectal lymph nodes. Subsequently, the mucosa becomes hyperemic and friable, and bleeds on manipulation. Proctoscopy reveals multiple, discrete, superficial ulcerations which are subsequently replaced by granulation tissue. Chronic proctocolitis follows with the formation of non-caseous granulomas and crypt abscesses. Symptoms of proctocolitis include fever, rectal pain, tenesmus, and a mucoid blood-stained discharge, which turns mucopurulent due to secondary infection by the endogenous bowel flora.<sup>82,83</sup>

The inflammatory process involves all layers of the bowel wall (Fig. 41.7). Over a period of 3–6 months, it is gradually replaced by fibrous tissue. As a result, the anorectal mucosa becomes rugose and rigid. The fibrous tissue contracts over a period of months to years leading to formation of rectal strictures and rectal stenosis.

**Fig. 41.7:** Contrast-enhanced computerised tomography scan of the pelvis of a patient with anorectal-genital LGV showing mural thickening of the rectum with presence of perirectal stanching. There is loss of the fat plane between the rectum and the left seminal vesicle. The patient complained of constipation and difficulty in defecation. Courtesy: Dr. Naveen Kalra, Chandigarh, India.

Rajam and Rangiah have described three types of strictures: annular, tubular and funnel-shaped. Annular strictures are the most common type (64%), usually situated 2–5 cm above the ano-cutaneous junction. They may be rigid and non distensible, or resilient and diaphragmatic. The proximal mucous membrane is ulcerated while the distal end is usually normal. In the end, the ulcers can lead to the perforation of the bowel wall and cause a peritonitis. Patients with this type of stricture experience chronic constipation, recurrent attacks of ileus with colic, abdominal distension, weight loss, and passage of “pencil” stools. In the tubular type, the entire bowel length below the pelvi-rectal junction is converted into a rigid, narrow tube with multiple constrictions along its length. In the funnel type, there is progressive narrowing from below upwards with the upper limit at the ampula of rectum. The anorectal and pararectal lymph nodes below the stricture suppurate to form perirectal and ischio-rectal abscesses. Supralelevator abscess formation mimicking rectal cancer has also been described.<sup>84</sup> These abscesses can rupture causing fistulae. Rectal adenocarcinoma may develop in 2–5% of patients with long-standing rectal strictures.<sup>85</sup> Lymphatic and venous obstruction of the lower rectum by the fibrotic process produces perianal outgrowths composed of dilated lymph vessels with perilymphatic inflammation, referred to as “lymphorrhoids” and mimicking perianal condylomata.

### Urethro-genito-perineal Syndrome

Long-standing disease in women results in papillary growths on the mucosa of the urethral meatus. It causes dysuria, frequent urination, urinary incontinence, and perimeatal ulceration. In men, penile, scrotal, or perineal sinuses may develop with or without urethral stenosis.

### OCULAR MANIFESTATIONS

Eye involvement may occur at any stage of the disease due to autoinoculation with the infectious discharge. The condition is commonly caused by *C. trachomatis* biovar L2 and is analogous to Parinaud oculoglandular syndrome. It manifests as mixed papillary-follicular conjunctivitis accompanied by submaxillary and posterior auricular lymphadenopathy. A hypersensitivity reaction to the antigen presenting as bilateral conjunctivitis, episcleritis, keratitis, or iritis, and occurring in association with the inguinal or anorectal syndrome has also been reported.<sup>1</sup>

### CUTANEOUS MANIFESTATIONS

Cutaneous lesions are attributed to a hypersensitivity reaction to the LGV antigens (id eruption or ide reaction) and present as transient generalized exanthemata, widespread papules, pustules, nodules, scarlatiniform eruption, urticaria, erythema multiforme, erythema nodosum, and erythema annulare centrifugum.<sup>77</sup> A photoallergic dermatitis (probably due to an allergic reaction to the toxins), manifesting as recurrent itchy papular and papulo-vesicular eruptions on sun-exposed regions has been described.<sup>77</sup> It usually occurs in association with the inguinal or anorectal syndrome.

## OTHER EXTRAGENITAL MANIFESTATIONS

LGV tonsillitis and primary LGV of the mouth and pharynx may occur as a result of receptive oral sex.<sup>39,73</sup> It is associated with cervical or submaxillary lymphadenopathy. Axillary lymphadenopathy has been reported due to accidental infection among doctors, nurses, or laboratory workers handling infectious material.<sup>1</sup> Cases of supraclavicular lymphadenitis in association with mediastinal lymphadenopathy and LGV pericarditis have been reported.<sup>86</sup> Chronic cholecystitis secondary to LGV has been documented with the organism isolated from gall bladder wall. There are also reports of LGV presenting as a psoas abscess.<sup>87</sup> Recently, a case of reactive arthritis has been reported occurring after the development of proctitis due to *C. trachomatis* L2b biovar.<sup>88</sup>

## LGV and HIV and Hepatitis C

In the current LGV epidemic among MSM, the majority are co-infected with HIV (approximately 80%),<sup>15–17,71,89,90</sup> but hepatitis C is also found in up to 18%.<sup>15,91</sup> Until recently hepatitis C was not considered as a sexually transmissible pathogen. Nonetheless, there are strong indications that in the current LGV epidemic among MSM, hepatitis C infections were acquired through high risk sexual contacts.<sup>92</sup> Because LGV is an ulcerative disease, the transmission of blood borne diseases like hepatitis C but also HIV is possibly facilitated. During a retrospective analysis of 27 cases of LGV seen in a Paris hospital, 6 cases with concomitant HIV infection were found.<sup>74</sup> However, HIV appeared to have no effect on the clinical presentation in these cases. Similarly, Heaton et al.<sup>93</sup> reported a case of a HIV-positive pregnant woman with uncomplicated LGV. In a South African study comprising 45 HIV-infected patients compared to 8 non-HIV-infected patients with LGV the clinical presentations of LGV were similar for both groups.<sup>37</sup>

A few studies have demonstrated reactivation of latent LGV with the development of multiple groin abscesses in HIV-positive patients.<sup>30</sup> Buus et al.<sup>94</sup> reported an atypical presentation of Parinaud oculoglandular syndrome consisting of unilateral follicular conjunctivitis with superior marginal corneal perforation in association with preauricular and inguinal lymphadenopathy due to *C. trachomatis* biovar L2 in an HIV-positive patient. The patient responded well to topical cefazolin and gentamicin, oral tetracycline, and surgical management. In both HIV-positive and negative cases, the diagnosis can be established by high chlamydial complement fixation antibody titers (>1:64).<sup>95</sup> Yet, Nucleic Acid Amplification Tests (NAAT) are the preferred diagnostics nowadays (see below). Centers for Disease Control and Prevention recommends the same treatment regimen for LGV in HIV-positive and negative patients.<sup>96</sup>

## Differential Diagnosis

The diverse presentations of LGV make it extremely difficult to establish a definitive diagnosis by clinical examination alone. The variability of presentation during different stages of disease

evolution poses a great challenge in differentiating it from other dermatological and sexually transmitted diseases (Table 41.3).<sup>97–100</sup>

The primary stage, characterized by an evanescent, painless papule, erosion or ulcer, is often missed by the clinician. It may simulate genital herpes, primary syphilis, chancroid or traumatic ulceration. A mucopurulent urethritis noted in a few instances of LGV, is often mistaken for non-specific urethritis or gonorrhea. A balanoposthitis like picture mimicks bacterial, candidal or traumatic balanoposthitis.<sup>30</sup> In a report by Zweizig et al.,<sup>101</sup> the clinical presentation and tomographic findings in a patient with primary inoculation LGV of the cervix were suggestive of cervical cancer.

The second stage of LGV manifests as regional lymphadenitis and perilymphangitis with bubo formation. It is usually associated with fever and constitutional symptoms. The involved lymph nodes are tender, matted and form multilocular abscesses that rupture to form multiple discharging sinuses. The primary genital lesion is usually absent at this stage. This condition poses a diagnostic dilemma and is often confused with the bubo of chancroid, syphilis, genital herpes, plague, tularemia, tuberculosis lymphadenitis, cat-scratch disease, septic lymphadenitis, Hodgkin disease, incarcerated inguinal hernia, or psoas abscess.<sup>102</sup>

In the tertiary stage, genital elephantiasis may mimic filariasis, tuberculosis, fungal, or parasitic infection, granuloma

**Table 41.3:** Differential Diagnosis of LGV

<b>Primary stage</b>
<ul style="list-style-type: none"> <li>• Genital herpes</li> <li>• Primary syphilis</li> <li>• Chancroid</li> <li>• Traumatic ulcer</li> </ul>
<b>Secondary stage (inguinal syndrome)</b>
<ul style="list-style-type: none"> <li>• Chancroid</li> <li>• Syphilis</li> <li>• Genital herpes</li> <li>• Plague</li> <li>• Tularemia</li> <li>• Tuberculosis</li> <li>• Cat-scratch disease</li> <li>• Septic lymphadenitis</li> <li>• Hodgkin disease</li> <li>• Incarcerated inguinal hernia</li> <li>• Psoas abscess</li> <li>• Kikuchi-Fujimoto syndrome</li> </ul>
<b>Tertiary stage - Genital elephantiasis</b>
<ul style="list-style-type: none"> <li>• Filariasis</li> <li>• Tuberculosis</li> <li>• Fungal infection</li> <li>• Parasitic infection</li> <li>• Granuloma inguinale (Donovanosis)</li> <li>• Toxemia of pregnancy</li> <li>• Anorectal syndrome</li> <li>• Inflammatory bowel disease (esp. Crohn disease)</li> <li>• Rectal stricture</li> <li>• Malignancy</li> <li>• Trauma</li> <li>• Actinomycosis</li> <li>• Schistosomiasis</li> </ul>

inguinale (pseudo-elephantiasis), or transient vulvar elephantiasis with toxemia of pregnancy.<sup>30</sup> The clinical and histologic picture of early LGV proctocolitis is similar to that seen in inflammatory bowel disease.<sup>30</sup> LGV proctitis has been mistaken for Crohns disease which has led to delay in the correct diagnosis, and suboptimal treatment.<sup>89,103</sup> The rectal strictures of LGV may resemble those caused by trauma, actinomycosis, tuberculosis, schistosomiasis, or adenocarcinoma of the rectum.

## Laboratory Diagnosis

### STANDARD DIAGNOSTIC PRACTICE FOR CLINICAL PURPOSES

LGV is a complex disease with varied clinical manifestations and is difficult to diagnose on clinical grounds alone. The gold standard diagnosis of LGV is made on the detection of biovar specific bacterial DNA in rectal specimens (in case anorectal LGV is suspected) or in genital ulcers or bubo aspirate (in case inguinal LGV is suspected), although the organism is difficult to detect in bubo aspirates. It is advised for budgetary reasons to follow a two-step procedure. First, a commercially available pan *C. trachomatis* Nucleic Acid Amplification Test (NAAT) can be used to screen suspected samples.<sup>104</sup> Although no commercially available tests are approved for extra genital sites, a large body of literature supports the use of these tests for the detection of rectal chlamydia infections.<sup>16,105–107</sup> If *C. trachomatis* is found, LGV biovar specific DNA needs to be sought. For this purpose, several “in house” NAAT tests have been developed. These tests can discriminate different *C. trachomatis* serotypes based on specific epitopes on the major outer membrane protein A (MOMP).<sup>108</sup> Firstly, a real-time polymerase chain reaction based test that specifically detects all *C. trachomatis* LGV biovar strains developed by Morré et al.<sup>7</sup> The second test is a real-time quadriplex PCR assay that incorporates an LGV specific target, a non-LGV-specific target sequence, a *C. trachomatis* plasmid target, and the human RNase P gene as an internal control as described by Chen et al.<sup>6,109</sup> These methods discriminate between LGV and non-LGV biovar types only, which is sufficient for clinico-diagnostic purposes. Recently, commercial tests have become available, which can discriminate 15 different *C. trachomatis* biovars, including the different LGV specific ones.<sup>110</sup> These tests can also be used to diagnose LGV.<sup>111</sup> In case molecular diagnostic test facilities are not at hand a presumptive LGV diagnosis can be made using chlamydia specific serological assays. A high antibody titer in a patient with complaints suggestive of LGV supports the diagnosis. Nonetheless, a low titer does not rule out LGV, nor does a high titer in a patient without LGV symptomatology prove LGV infection.<sup>16,43</sup> Although it has been stated that an elevated chlamydia specific IgA and IgG titer is associated with LGV,<sup>112</sup> asymptomatic LGV infections require LGV specific NAAT assays for accurate diagnosis.<sup>113</sup>

### GENOME SEQUENCE ANALYSIS NOT FOR DIAGNOSTIC PURPOSES

Recent advantages in genome sequence analysis has been used to elucidate the origin of LGV outbreaks and the specific clinical characteristics of LGV.<sup>114</sup> Multilocus Sequence Typing (MLST) is a genotyping method based on amplification and sequencing of several genetic regions.<sup>115</sup> It has been used to deduce the nature and origin of the LGV outbreak among MSM in Europe.<sup>116</sup> In combination with single nucleotide polymorphism (SNP) analysis, MLST is a promising tool for epidemiologic and evolutionary studies of LGV populations worldwide.<sup>117</sup>

### HEMATOLOGICAL INVESTIGATIONS

The hematological and biochemical investigations suggestive of LGV include mild leukocytosis, monocytosis, and eosinophilia, increase in total serum proteins due to raised IgG, IgA and IgM levels with reversal of the albumin:globulin ratio, and raised erythrocyte sedimentation rate (ESR).<sup>118</sup>

### FREI TEST

The Frei test is based on a delayed type hypersensitivity reaction on LGV specific antigen, but has become obsolete now and the antigen is not available commercially. It is an intradermal test for the diagnosis of present or past LGV infection and remains positive for life. It shows cross-reactivity with other chlamydial infections such as psittacosis, and with cat-scratch disease.

### CHLAMYDIA CULTURE

#### Specimen Collection

Appropriate sites for specimen collection for chlamydia isolation are the rectal mucosa, urethra and cervix. In bubo pus the correct diagnosis is often missed due to the high concentrations of digesting enzymes which break down bacterial antigens and often interfere with current diagnostic tests. Rayon and PET fiber swabs are superior to cotton or calcium alginate. Due to the invasive nature of the L biovar causing LGV disease, the best material for LGV diagnostics are biopsies including both mucosa and underlying connective tissue from infected sites.<sup>119</sup> Since obtaining a biopsy comprises an invasive procedure it cannot be performed in all settings, and swabs from mucosal linings are the second best option. The cytobrush, a small brush on a wire or a plastic shaft, is an excellent device for collecting cervical or rectal specimens. It collects more material compared to non-rigid devices and increases the sensitivity of Chlamydia detection methods.

### Sampling Sites

- **Bubo:** The bubo pus is collected by aspirating with a wide-bore needle if it is fluctuant. If it is not fluctuant, sterile saline

is injected and then aspirated. Before inoculation on tissue culture, the specimen is homogenized in the culture medium to obtain a 10–20% (w/v) suspension and inoculated in a 1:10 to 1:100 dilution.

- **Rectum:** Specimens are collected using an anoscope for the direct visualization of erythematous, friable mucosa, and areas of mucopus. The swab is inserted 3 cm into the anal canal and rotated for 10 seconds to collect exudate from the crypts just inside the anal ring. Since the rectal specimens frequently cause contamination or cytotoxicity in tissue culture, it is advisable to sonicate them prior to inoculation.
- **Urethra:** A thin swab is introduced 3–4 cm into the urethra and the mucosa is scraped by rotating the swabs for 5–10 seconds.
- **Cervix:** Before obtaining the specimen, the exocervix is cleaned to remove external secretions. The swab is inserted 2 cm into the cervical canal and rotated for 10 seconds to gently scrape the epithelial cells.
- **Eye:** The eyelid is everted and epithelial cells are collected by rubbing a swab over the conjunctival mucosa.
- **Throat:** The specimen is collected from the region of tonsillar crypts and posterior pharynx.

## Specimen Transport

The specimens for tissue culture are inoculated and transported in cryovials containing 0.8–1 ml of the transport medium, such as sucrose phosphate medium or phosphate-buffered sucrose solution containing fetal calf serum and antimicrobial inhibitors. Immediate inoculation of the specimen (<2 hours) on to tissue culture cells yields the highest rate of success. If they are to be processed within 24 hours, specimens are refrigerated at 4°C immediately after collection. For longer periods (>24 hours), the specimen is frozen and stored at –70°C.

## Culture

Cell lines that have been widely used for *C. trachomatis* isolation include certain clones of HeLa 229, baby hamster kidney cells (BHK-21), and McCoy cells. The culture technique involves inoculation of clinical specimens into cycloheximide-treated McCoy cells (since cycloheximide reduces the metabolic activity of eukaryotic cells) or DEAE treated HeLa cells.<sup>9</sup> The cells are incubated at 36–37°C for 72 hours, stained with 0.5 ml of 5% iodine solution for 5–10 minutes and examined microscopically for the presence of typical dark-brown inclusions surrounded by a halo. Some laboratories prefer Giemsa staining, since Giemsa-stained cells can be visualized by dark-field microscopy.<sup>120</sup> An alternative is use of the immunofluorescence technique with fluorescein-labeled monoclonal antibodies. It is a very sensitive method, especially in asymptomatic cases, since greater number of inclusions can be detected in a short period.<sup>121</sup>

The reported recovery rate by culture from the buboes, genital or rectal tissue varies from 24–30%.<sup>122</sup> LGV-Chlamydia can also

be isolated by inoculation in mouse brain or the yolk sac of chick embryo with recovery rates of 98% and 78%, respectively.<sup>123</sup> The biovar L2 has also been isolated from an infected bubo in an endothelial cell culture system.<sup>124</sup>

## CYTOLOGY

The elementary bodies (EBs) and reticulate bodies (RBs) can be visualized in tissue scrapings by staining with Giemsa, Brown–Hopp hematoxylin and eosin, Warthin–Starry, Grocott methenamine silver, or phosphotungstic acid hematoxylin stains.<sup>61</sup> In the Giemsa stained smears, EBs appear purple, while the intracytoplasmic inclusions in epithelial cells containing RBs are basophilic and stain blue. Cytoplasmic areas around the inclusions appear grey whereas the nucleus stains pink. The development of fluorescein-labelled monoclonal antibodies directed against species-specific epitopes of major outer membrane protein also allows direct visualization of EBs.<sup>125</sup> It is a rapid diagnostic test, but interpretation of individual specimens is laborious and is recommended only when a relatively low number of specimens have to be processed. Chlamydial EBs appear as bright apple-green pin-points and the cells are counter stained red. Any particle, debris or artefact showing yellow-green fluorescence is a source of false-positive results. This technique shows acceptable accuracy for symptomatic patients, but lacks sensitivity in asymptomatic subjects who harbor lower numbers of organisms at sites of infection. Immunohistochemical examination can be performed using the avidin-biotin method.<sup>3</sup> This modality has a lower sensitivity as compared to culture and the presence of mucus, cell debris, microorganisms, and a small number of infected cells hamper microscopic diagnosis.

## HISTOPATHOLOGY FOR IDENTIFICATION OF CHLAMYDIA IN INFECTED LYMPH NODES

The major diagnostic feature of LGV in the lymph nodes is the presence of vacuolated macrophages with intravacuolar organisms. The RBs line the vacuolar membrane and the smaller EBs are scattered throughout or are clumped inside the vacuole. These vacuoles, although most prominent at the margin of suppuration, may be present in the centre of the abscess or lie within the periphery of the mantle of lymphoid follicles. Clusters of monocytoid B-cells assemble at the periphery, particularly in subcapsular or paratrabeular spaces. Microabscesses develop at the junction of the vacuoles and B-cells, or within clusters of B-cells. In well-formed secondary follicles, fibrin deposits form intercellular networks from the margin of affected germinal centers inwards, often in a crescent shape. At the margin of the follicle, monocytoid B-cells expand the subcapsular and paratrabeular spaces. Macrophages intersperse among the B-cells, and abscesses expand within or adjacent to B-cells. Expanding abscesses penetrate the mantle and impinge upon the germinal center. A wreath of macrophages forms around the abscess with an outer

collar of B-cells. Pools of extracellular organisms lie inside the margin of the abscess. Also adjacent to the abscesses, the vascular endothelial cells are prominent and narrow the lumen. In other areas of the lymph node, there are foci of hemorrhage. The capsule may become focally thickened. Electron microscopy reveals small spherical intracytoplasmic vacuoles dividing by binary fission. These organisms appear in three different forms. The largest, 1.9  $\mu\text{m}$  in diameter, have evenly distributed ribosomes surrounded by cytoplasmic membrane. In larger vacuoles, 0.2–0.4  $\mu\text{m}$  diameter microorganisms with an eccentrically located electron-dense nucleoid structure, coarse electron dense ribosomes and well-defined cell wall and cytoplasmic membrane are present, and these are identical to EB. Intermediate bodies have a centrally condensed nuclear region separated from peripherally located ribosomes by an electron-transparent space.

## ANTIGEN DETECTION

### Enzyme Immunoassays (EIAs)

This method is suitable for antigen detection in ulcer scrapings or bubo aspirates but not for rectal samples. It has a sensitivity of 75–80%.

### Rapid Assays

Rapid assays, or “point of care tests” for *C. trachomatis* antigen detection, giving results within 30 minutes, have recently been developed.<sup>126</sup> These assays require a minimum of direct “hands on” manipulation, need no sophisticated equipment, and permit rapid diagnosis in field conditions. Several rapid assays have been made commercially available for the detection of urogenital *C. trachomatis* infections. None discriminates between LGV and non-LGV biovars, which makes their use for LGV diagnostics limited. Moreover, the sensitivity of most of these tests are disappointingly low to detect urogenital Chlamydia infections.<sup>126</sup> Better results with a sensitivity up to 80% have been claimed by some of the newer versions of these “point of care tests.”<sup>127</sup> To date, no information is available on the diagnostic use of these rapid assays for the detection of LGV infections.

## ANTIBODY DETECTION

The serological methods have limited use in the diagnosis of acute LGV infection.<sup>128</sup> While the detection of high levels of IgG antibody (titer of 1:256) may support the diagnosis of LGV, the presence of IgM (serum titer of 1:32) is more valuable. Diagnostic evidence can be obtained by demonstration of seroconversion in paired sera. Antibodies to LGV-Chlamydia can be detected by various serologic tests.

### Complement Fixation Test (CFT)

This is the most widely used serologic test.<sup>129</sup> It becomes positive after 1–3 weeks of infection. A CFT titer of 1:64 indicates active LGV infection and is observed in 50% of the patients.

Occasionally, high titers may be found in asymptomatic patients and those with other chlamydial infections. This test has a sensitivity of 80% for LGV. It does not reflect the efficacy of treatment or the progress of disease.

### Microimmunofluorescence Test (MIF)

It is the most accurate serologic assay.<sup>8</sup> It uses formalin-fixed EBs grown in yolk sac as antigen. During the active phase of LGV, patients show high levels of IgM (titers > 1:32) and IgG (titers > 1:512) with the antigen type of the infecting strain and much lower cross-reactivity with other *C. trachomatis* strains. However, preparation of the antigen for this test is complex and laborious and to date, the use of MIF has been limited to a few research laboratories. Ready-to-use antigens are not widely available.

### Single L-type Chlamydial Fluorescence Test

This test utilizes chlamydial inclusions from a tissue culture infected with LGV-L2 strain.<sup>130</sup> It is more sensitive than CFT but crossreacts with the other biovars of *C. trachomatis* and *C. pneumoniae*. The test may be useful for screening populations for epidemiological purposes, but not for diagnosis.

### Radioisotope Precipitation Test (RIP)

This test is more sensitive than the MIF test.<sup>70</sup> In this procedure, antiglobulin is used to precipitate radioactive-labeled and soluble chlamydial antibody. The proportion of radioactivity removed from the system is a measure of the amount of antibody present.

### Neutralizing Antibody Test

In this test, serum is combined with virulent mouse brain emulsions and inoculated intracerebrally.<sup>70</sup> If the test serum contains LGV antibody, the inoculated mixture does not cause meningo-encephalitis.

### Immunoperoxidase Test

It is a simple and rapid test for detecting *C. trachomatis* specific IgG and IgA antibodies.<sup>13</sup> IgG titer greater than 1:128 and IgA greater than 1:16 is suggestive of active infection. It has been found to be positive in 83.3% cases of LGV.

ELISA and counter immune electrophoresis (CIEP) are other serologic tests for the diagnosis of LGV.<sup>41,131</sup>

## IMMUNOTYPING OF ISOLATES (MONOCLONAL ANTIBODIES)

This is primarily of research interest, but may be used for epidemiological purposes. Biovar-specific monoclonal antibodies have been developed and two methods, microimmunofluorescence, and immunodot enzyme immunoassay, may be used as test procedures.<sup>132</sup> In a study, monoclonal antibodies raised against LGV biovars L1 and L3 were able to establish a diagnosis in 68% and 16% of cases, respectively.<sup>133</sup>

## RADIOLOGICAL INVESTIGATIONS

Computerized tomographic scan or magnetic resonance imaging of the abdomen and pelvis may be useful if retroperitoneal adenitis or an intra-abdominal abscess is suspected.<sup>1</sup> It may also help in assessing the extent of inflammation in rectum and anorectal stricture (Fig. 41.7). Lymphangiography does not outline buboes, but may demonstrate the extent of lymph node involvement. Barium enema may reveal elongated strictures in rectal LGV.

## Treatment

The goal of therapy is to eradicate the pathogen. Medical treatment is of immense value in the acute phase of the disease such as acute bubo, ulceration, draining sinuses, proctitis, and colitis.<sup>134</sup> Early and prompt treatment is essential to prevent disease transmission, serious complications, and mutilating sequelae. There is paucity of controlled double-blind treatment trials for LGV in the literature. The low incidence of the disease, its complex presentation and the natural history marked by spontaneous remissions and exacerbations have precluded any rigorous evaluation of management. Nevertheless, sporadic trials have shown successful use of sulfonamides,<sup>135</sup> tetracyclines,<sup>136</sup> minocycline,<sup>137</sup> and erythromycin<sup>138</sup> in the treatment of LGV. With early and prompt treatment, it has been shown that the duration of buboes is reduced, ulcers rapidly heal, sinuses cease to drain, and rectal discharges abate.<sup>134</sup> Prolonged treatment (at least for 3 weeks) is the norm and more than one course of therapy or alternating some of the antibiotics may be necessary for chronic cases. It has been shown that L biovar *C. trachomatis* RNA can persist for up to 16 days in LGV proctitis patients treated with doxycycline, whereas nucleic acid from non-LGV biovars was undetectable after 7 days.<sup>139</sup> On the basis of the known response of *C. trachomatis* to antibiotics in uncomplicated infections, the following recommendations have been made:

- **World Health Organization (2003):** Doxycycline, 100 mg orally twice a day × 2 weeks, or Erythromycin, 500 mg orally, 4 times a day × 2 weeks, or Tetracycline, 500 mg orally, 4 times a day × 2 weeks, or Sulfadiazine, 1 g orally 4 times a day × 2 weeks
- **Centers for Disease Control and Prevention (2010)<sup>96</sup>:** Doxycycline, 100 mg orally twice a day × 21 days, or Erythromycin, 500 mg orally 4 times a day × 21 days, or Azithromycin, 1 g orally once weekly × 3 weeks.
- **Other Treatment Modalities:** Minocycline, 300 mg orally initially, followed by 200 mg twice a day for 10 days has been successfully used in treating acute bubonic LGV and LGV proctocolitis.<sup>137</sup>
- Rifampicin, 450 mg in a single daily dose for 10 days has been found useful. Azithromycin, single 1 g oral dose is effective in uncomplicated infection.<sup>140</sup> An alternative regimen of azithromycin single 1 g orally with doxycycline, 100 mg twice a day for 7 days was also found useful.

- **Children and Pregnancy:** For pregnant and lactating women or children below 8 years, erythromycin stearate is prescribed.<sup>99</sup> In children, the dose is 7.5–12.5 mg/kg/dose four times a day for 2 weeks.

## SURGICAL TREATMENT

The chronic manifestations of LGV such as genital elephantiasis, vulval growths, esthiomene, or rectal strictures and stenosis do not respond to antibiotic therapy and require surgical intervention and plastic reconstruction. For buboes, hot fomentation may be advised. Fluctuant buboes are aspirated through the surrounding normal skin with a wide bore needle, and not incised.<sup>141</sup> Rectal strictures are dilated either manually or with elastic bougies at weekly intervals. When the stricture is impassable, a preparatory ileo-colostomy followed by proctocolectomy is a justifiable procedure.<sup>30</sup> Chronic intractable ulcerative lesions of the rectum may be treated by suitable single-stage surgical procedures, such as full skin cover by direct flaps, myocutaneous flaps, or sliding flaps (floating island).<sup>102</sup> A urethral stricture can be dilated with Lister's or Clutton's bougies.<sup>30</sup> Perianal and perirectal abscesses must be surgically drained. Surgical repair of recto-vaginal fistulae, esthiomene, and genital elephantiasis may be required. Polypoid excrescences of the vulva, pedunculated tumors or elephantiasic vulvae require local excision, and partial or total vulvectomy.

## FOLLOW-UP

Patients without anatomical deformations due to the LGV infection who have received the standard antimicrobial therapy do not require clinical follow up visits. In case of anatomical defects like fistulae, strictures or sinuses that possibly require surgical intervention need to be followed up until their complaints have been dealt with.

## PARTNER MANAGEMENT

Subjects who have had sexual contact with an LGV patient within 6 months before the onset of the patient's symptoms, or in case of asymptomatic cases at the time of diagnosis, should be examined, tested for chlamydial infection and promptly treated empirically.<sup>30</sup>

## Prevention

In endemic areas, LGV can be prevented by practicing safe sexual habits such as use of condoms and avoidance of casual sexual contact, particularly with sex workers. Enema use prior to receptive anal sex should be discouraged since it is associated with rectal chlamydial infections, and especially LGV proctitis.<sup>15</sup> Sexual contacts must be traced and promptly treated. Patients on antibiotic therapy should be monitored for recurring symptoms over a period of 6 months following antibiotic treatment.<sup>26</sup> Doctors and other healthcare workers must observe proper safeguards such as wearing gloves when touching infected sites or handling soiled dressings or other contaminated items. Health-

seeking behavior and health education of those at risk should be encouraged.

## Conclusion

LGV is a serious STI caused by the invasive *C. trachomatis* L biovar. The wide variety of symptoms ranging from acute inflammatory disease to chronic mutilating sequelae can cause a diagnostic dilemma for the clinician. Physicians should consider LGV in patients with inguinal lymphadenopathy, genital ulceration, fistulae, or anorectal complaints. Although it used to be confined to equatorial areas, an on going LGV epidemic among MSM in the Western world has emerged since 2003. There is a need for better and cheaper screening tools to detect cases in larger groups of individuals at risk. This is of importance to prevent complications in the individual patient and to halt transmission in the community. Shorter antibiotic courses than the present ones of 21 days are needed to increase patient compliance to the treatment but require large controlled clinical trials. Lastly, a deeper understanding of the microbial and immunological background of LGV infection could shed light on the invasive nature of the LGV biovars, which contrasts the inert infections caused by the non-LGV *C. trachomatis* biovars.

# 42

## Introduction

Chancroid is a sexually transmitted infection (STI) of the genitoinguinal area caused by the bacterium, *Haemophilus ducreyi*. It manifests clinically with single or multiple, superficial, tender ulcers over the anogenital region. Painful inguinal lymphadenitis with or without bubo formation may occur in half of the patients. Chancroid is one of the major causes of genital ulcer disease (GUD), and constitutes an important cofactor in the transmission of HIV infection in many resource-poor countries of Africa, Asia, and Latin America.<sup>1</sup>

## Historical Aspects

According to Kampmeier, chancroid was first described in 1852 (France) by Ricord and Bassereau as *ulcus molle* differentiating it from the hard chancre of primary syphilis.<sup>2</sup> In 1889 Augusto Ducrey, a bacteriologist at the University of Naples, performed a series of autoinoculations on the forearms of patients with purulent material from their own genital ulcers, and established *H. ducreyi* as the etiological agent of chancroid.<sup>3</sup> Bezancon et al. are often credited for the first significant isolation of *H. ducreyi*.<sup>4</sup> Unna described the histopathology of chancroid, and observed clumps and chains of gram-negative rods in tissues.<sup>5</sup>

Ito introduced intradermal testing with *H. ducreyi* obtained both from culture and with pus from a chancroidal bubo in 1913. The appearance of a papule 8 mm or more in diameter between the 3rd and 7th day was considered confirmatory.<sup>6</sup> This was later validated by Reenstierna in 1921 at the Pasteur Institute, and the diagnostic value of the Ito-Reenstierna test was further evaluated by Greenblatt et al.<sup>7</sup> However, this test is now only of historical importance as the antigens are no longer available.

## Epidemiology

According to a World Health Organization (WHO) report, an estimated 7 million cases of chancroid occur annually across the globe.<sup>8</sup> The true global epidemiology is unclear since chancroid cannot be reliably differentiated from other GUDs on clinical

grounds and there is a lack of readily available diagnostic tests in most clinics. The disease however is prevalent worldwide, and endemic in many poor countries of tropical and subtropical regions with inadequate medical infrastructure, especially sub-Saharan Africa, Asia, and Latin America.<sup>9,10</sup>

The pattern of GUD is changing rapidly with studies from Africa revealing that GUD attributable to herpes simplex virus (HSV) type-2 infection is increasing, and that of *H. ducreyi* is decreasing in many areas.<sup>11</sup> A gradual decline in the prevalence of *H. ducreyi* was noted among patients attending an STI clinic in Durban (South Africa), from 35% in 1995 to 6% in 1998. During the same period, HSV-2 infection rose from 11% to 45%.<sup>12</sup> Since the mid-1960s, the incidence of chancroid has been decreasing in many parts of Africa and Asia, especially Kenya, Senegal, Philippines, and Thailand. This may partially be a consequence of intervention strategies targeting commercial sex workers (CSWs) and STI patients to prevent HIV transmission.<sup>1</sup> In Nairobi, Kenya, chancroid was endemic but now accounts for less than 10% of genital ulcers. The number of reported cases of chancroid has declined steadily in the USA from 4986 cases in 1987 to 143 cases in 1999.<sup>13</sup> More recent CDC statistics reveal that chancroid is disappearing in the United States, with only 23 cases reported nationwide in 2007.<sup>14</sup> In the United Kingdom, 378 new episodes of tropical GUD (combining chancroid, LGV, donovanosis) were seen at the genitourinary medicine clinics in 2008. England accounted for 367 (97%) episodes, of which 183 (almost 50%) were seen in London. These figures were mainly due to the recent epidemic of LGV.<sup>15</sup> Chancroid is rare in the Scandinavian countries and Australia.<sup>16,17</sup> Chancroid is endemic in some parts of India, and its prevalence has varied from 1.6% to 51.9% based on reports from different STI clinics.<sup>18–20</sup> The wide variation may be due to the lack of uniform diagnostic criteria besides diverse social, cultural, and religious practices prevailing in the local population. The prevalence of chancroid has been reported to be 22.4% among children below 14 years of age with STIs in Delhi.<sup>21</sup>

Chancroid is seen more frequently in the sexually active age group of 18–45 years. Men are more commonly affected, with

the male to female ratio exceeding 10:1 (varying from 1.6:1 to 53:1).<sup>22–24</sup> Important factors contributing to the gender disparity, may be the possibility of fewer women transmitting the infection to a large number of men through commercial sex, an asymptomatic carrier state in women,<sup>25</sup> and the concealed and subclinical nature of lesions on the female genitalia resulting in unhampered sexual activity. It also appears that an occlusive environment provided by the prepuce makes men more susceptible. A recent meta-analysis revealed that circumcised men were clearly at a lower risk of chancroid.<sup>26</sup>

The disease is almost always contracted through sexual contact, barring minor episodes where medical professionals acquire the infection on fingers through accidental inoculation. Plummer et al. have reported that the chances of acquiring infection during a single act of unprotected exposure from man to woman are as high as 63%.<sup>27</sup> In the absence of treatment, the duration of infection has been estimated to be 45 days in women, and it appears that the risk of transmission is much more with patients bearing visible lesions.<sup>28</sup> Fomites do not play a role in the transmission of the disease. There is no nonhuman reservoir for *H. ducreyi*, and it depends for its survival and propagation on sexual transmission. Individuals with poor hygiene and CSWs constitute a major source of infection. Alcoholism and cocaine abuse in the smoked form (“crack”) are also associated with an increased risk.<sup>29,30</sup>

## Biology

*H. ducreyi* is a pleomorphic, slender ( $1.2 \times 0.5 \mu\text{m}$ ), gram-negative, nonmotile, nonspore forming, and facultative anaerobic streptobacillus with rounded ends. It is a fastidious organism with complex nutritional requirements for its growth. It has some characteristic biochemical properties, which include a reaction positive for oxidase and alkaline phosphatase activity, and negative for catalase activity. It reduces nitrate to nitrite and requires hemin (X-factor) for growth. In liquid culture or tissue the organisms form parallel chains resembling “railroad tracks”, while on solid agar “schools of fish” and whorls appear which resemble “fingerprints”.<sup>31</sup> Recent genetic sequencing data has revealed that *H. ducreyi* is more closely related to the animal pathogens *Actinobacillus pleuropneumoniae* and *Mannheimia haemolytica* than to human pathogens in the Pasteurellaceae family. However, animal models of chancroid do not adequately simulate human infection, suggesting that *H. ducreyi* has deviated from other organisms to establish itself as a unique human pathogen.<sup>32</sup>

## Pathogenesis

The exact pathogenesis of ulcer formation in chancroid is not clear. The organisms appear to enter sites of trauma or abrasion where the integrity of skin is disrupted. The inoculum size has to be more than  $10^4$  to produce an infection.<sup>33</sup> Adherence of bacteria to the epithelial cells is mediated by pili, and the subsequent production of hemolysins and cytotoxins results in cell damage. Both cell-mediated and humoral responses occur to infection with chancroid. A delayed hypersensitivity reaction and recruitment of

peripheral blood mononuclear cells is seen in response to specific *H. ducreyi* antigens. The cell-mediated response to *H. ducreyi* infection is predominantly of Th-1 cells. Immunohistological studies have revealed a predominant mononuclear infiltrate consisting mainly of CD4+ and CD8+ T-lymphocytes, and monocytes with a conspicuous paucity of B-lymphocytes in the biopsy specimens of chancroid lesions. This predominant T-helper cell (Th1) response is consistent with the observation of increased levels of soluble interleukin-2 receptors in the urine and semen of chancroid patients.<sup>34</sup> These cytokines are secreted by CD4+ T lymphocytes.

A humoral response with production of IgG, IgM, and IgA occurs but does not confer lasting immunity. Many antigens, including the major outer membrane protein (MOMP) with a molecular weight of 40 KDa, have been characterized and the cell wall bears pili. The exact role of the various cytotoxins and hemolysins in pathogenesis is not clear, though they are thought to participate in tissue damage and ulcer formation. The virulence factors associated with *H. ducreyi* are likely to be the lipooligosaccharide (LOS), pili, extracellular toxins, and hemolysins.<sup>33,35–37</sup>

Chancroidal lymphadenitis is predominantly a pyogenic inflammatory response, with an unknown pathogenesis; the paucity of organisms in the bubo pus is also unexplained. Virulence determinants in the organism include superoxide dismutase enzymes and hemolysin. Superoxide dismutase enzymes are thought to increase the survival and persistence of the pathogenic organism within the host, whereas hemolysin contributes to ulcer formation and the invasion of epithelial cells.<sup>35</sup> The latter has immunogenic properties and is expressed both *in vitro* and *in vivo* by all known clinical strains of *H. ducreyi*. These properties make hemolysin a possible candidate for vaccine development.<sup>38</sup>

## Clinical Features

The incubation period is usually short and varies from 3 to 7 days, except in patients with concomitant HIV infection where it can be longer. The lesion may occur within 48 hours, if there are abrasions present over the genitalia at the time of intercourse. An erythematous papule appears at the site of entry of the organisms, which turns into a pustule, undergoes central necrosis and forms a characteristic, small, necrotic, tender, bleeding, nonindurated ulcer with ragged or undermined edges (Fig. 42.1). Autoinoculation may result in the formation of kissing ulcers or multiple ulcers in proximity to the primary ulcer (Fig. 42.2).

Men usually present with painful genital ulcer(s) and/or a painful inguinal mass, and at times, phimosis or paraphimosis. There is no prodromal phase. Rarely, the patient may present with purulent urethritis if the ulcer is located in the urethra.<sup>39</sup> Genital lesions in women may be asymptomatic or may present with mild vaginal discharge, dyspareunia, pain on voiding, or defecation. Skin rash or systemic reactions are not encountered. The typical lesion of chancroid is a nonindurated (soft sore), painful ulcer with ragged or undermined edges and a necrotic base covered with purulent exudate. It bleeds easily on touch. Distinctively, the

**Fig. 42.1:** Irregular, necrotic ulcer with ragged margins surrounded by an inflammatory margin over the urethral meatus is seen.

**Fig. 42.2:** Multiple, small, necrotic ulcers with ragged borders over the penile shaft and kissing chancroidal ulcer over the coronal sulcus are seen.

ulcer is variably painful depending upon the site of inoculation. The pain is more in men than in women. The ulcers are often multiple, however, not uncommonly, a solitary ulcer can occur. *H. ducreyi* seems to have a predilection for the stratified squamous epithelium, the mucosa being rarely affected. Ulcers in men usually occur over the preputial orifice, inner prepuce, frenulum, coronal sulcus, penile shaft, and anal orifice. The common sites affected in women are the labia, clitoris, fourchette, vestibule, anal margin, and cervix. Due to autoinoculation, the lesions may later spread to the peri-inguinale region, mons pubis, abdomen, and thighs. The rare occurrence of extragenital lesions over the fingers, tongue, lips, breasts, oral mucosa, and perianal area has been reported.<sup>33</sup>

Various clinical patterns of genital ulcers in chancroid have been described.<sup>40–44</sup> *Dwarf chancroid* consists of single or multiple herpetiform ulcers with or without associated inguinal lymphadenopathy. *Giant chancroid*, initially a small ulcer, extends rapidly to form a solitary destructive lesion (Fig. 42.3). This form is often associated with an inguinal bubo. In *transient chancroid*, the initial lesion resolves rapidly within 4–6 days, only to be followed by acute inguinal lymphadenitis with suppuration in 10

**Fig. 42.3:** Giant chancroid over the glans penis showing necrotic ulcer surrounded by erythematous borders.

to 20 days. *Follicular chancroid* originates in the pilar apparatus, and therefore occurs on hair-bearing areas. *Phagedenic chancroid* is characterized by widespread necrosis with deep and often extensive destruction of the genitalia (Fig. 42.4). *Pseudogranuloma inguinale* is a variant of chancroid that bears close resemblance to granuloma inguinale.<sup>43</sup> In *serpiginous chancroid*, multiple ulcers coalesce to form a serpiginous pattern. In *mixed chancroid*, nonindurated, tender ulcers occur along with an indurated, nontender ulcer of syphilis. *Chancroidal ulcer* is usually a tender, nonindurated, single large ulcer with the conspicuous absence of lymphadenopathy, and is caused by organisms other than *H. ducreyi*.

**Fig. 42.4:** Phagedenic ulcer with edema of penile shaft.

## BUBO

Subsequent to appearance of a genital ulcer, the regional lymph nodes become tender and inflamed. Lymphadenopathy occurs in 30–60% of patients (both in men and women), usually 1–2 weeks after the appearance of the genital ulcers. It is unilateral in two-thirds of the patients. The typical bubo consists of inguinal lymph nodes that have become fused and matted together by an acute inflammatory process of periadenitis forming a unilocular swelling with erythematous overlying skin. The swelling is painful and causes difficulty in walking. The bubo softens and undergoes suppuration to form unilocular fluctuant swelling (Fig. 42.5), which may rupture spontaneously resulting in ulceration. The margins of the opening (ostium) are necrotic and inflammatory. In about half of the patients, the inguinal lymphadenitis may subside without suppuration. In contrast to the transient nature of the primary lesion seen in lymphogranuloma venereum (LGV), the genital ulcers in chancroid may persist when the patient presents with inguinal bubo.<sup>45</sup> Features that differentiate the bubo of chancroid from that of LGV are summarized in Table 42.1.

**Fig. 42.5:** Chancroid ulcer over the penile shaft and an inflamed bubo in the left inguinal area.

**Table 42.1:** Differentiating Features of Lymphadenopathy in Chancroid and LGV

Features	Chancroid	LGV
Frequency of involvement	30–60%	~100%
Incubation period (bubo)	7–14 days	10–30 days
Unilateral	75%	66.7%
Primary genital ulcer (when patient presents with bubo)	Present	Absent
Sinus formation from rupture of bubo	Single	Multiple
Constitutional symptoms	–	+
Systemic spread	–	+
Groove sign	–	+ (20% cases)
Loculation	Unilocular	Multilocular

## Clinical Course and Complications

Chancroid is a self-limiting disease presenting with no serious problems in the majority of cases. Pain is the most important complaint. The primary lesions heal gradually or may spread locally through autoinoculation. Inguinal lymphadenitis may be minimal and subside gradually or progress to form a bubo that may rupture leaving behind large ulcerations. Complications occur more frequently in men that include balanitis, phimosis, paraphimosis, and the partial loss of tissue over the glans penis in phagedenic ulcers due to superinfection with anaerobic organisms. Discharging sinuses and large areas of ulceration at the site of the inguinal bubo may result in scar formation. Systemic infection or metastatic spread to distant sites has not been reported.<sup>46</sup> However, mild constitutional symptoms may occur due to secondary infection of the ulcers.

## Laboratory Diagnosis

The laboratory confirmation of chancroid is essential for accurate diagnosis, management, and epidemiological monitoring. In suspected cases of chancroid, testing for herpes simplex virus and syphilis should also be performed. It is interesting that the accuracy of the clinical diagnosis of chancroid is greatly affected by the prevalence of the disease.<sup>47</sup> A comparison of studies that evaluated the accuracy of a clinical diagnosis of chancroid (Fig. 42.6) suggests that the diagnostic accuracy decreases with the prevalence of the infection declining in the given population.<sup>48–51</sup> Therefore, with a continuous decline in the prevalence of the disease, the reliability of clinical diagnosis diminishes and laboratory confirmation becomes essential.

## MICROSCOPIC EXAMINATION OF THE SMEARS

The ulcer is cleaned with saline and exudate from the undermined edge of the lesion is obtained by rolling a cotton or calcium alginate swab. This is then smeared onto a glass slide and stained

**Fig. 42.6:** Accuracy of clinical diagnosis of chancroid (in men) in relation to prevalence in various studies. Note, a consistent decline in the clinical diagnostic accuracy with a decline in the prevalence of chancroid among patients with genital ulcer disease.

**Fig. 42.7:** Smear from chancroid ulcer showing typical 'school of fish' appearance. Courtesy: SJ Wineslaus and JB Schofield, UK. Reproduced with permission from: Schofield JB, Wineslaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81.

with Gram, Unna-Pappenheim, Wright or Giemsa stains. The presence of typical streptobacilli lying in clusters, either inside the leukocytes or outside in chains, paralleling the shreds of mucus with the appearance of "schools of fish," "railroad tracks," and "fingerprints" may suggest a diagnosis of chancroid (Fig. 42.7). Often, it is difficult to demonstrate *H. ducreyi* in smears due to the polymicrobial flora of genital ulcers, which may resemble the *Ducreyi* bacillus. The organisms are less frequently demonstrated in the pus aspirated from a bubo, and culture from bubo is mostly sterile unless it has ruptured.<sup>3,52</sup> Some experts believe that direct microscopy of the smear is not reliable and should not be used in the routine diagnosis of chancroid.<sup>31</sup> It is of limited value because of low sensitivity (5–63%) and specificity (51–99%).<sup>53</sup>

### CULTURE AND IDENTIFICATION

Although *H. ducreyi* is a fastidious microorganism which is difficult to isolate from genital ulcer specimens, culture remains the main diagnostic tool, and for many years has been the "gold standard" for evaluating newer methods of diagnosis. However, even with the optimal combination of media, it is only about 80% sensitive. The specimen of choice is a swab that has been taken from the base of the genital ulcer.<sup>53</sup>

### Collection and Transport of Specimens

As *H. ducreyi* is a fastidious organism, it is essential that the specimens obtained from the base of ulcers or aspirate from the bubo should either be plated out directly onto the culture medium or sent to the microbiology laboratory rapidly (within 4 hours). The specimen should be obtained with a calcium alginate or plastic swab from the base of the ulcer after cleaning it with dry gauze. No selective transport medium is available, although Dangor et al. were able to grow relatively viable *H. ducreyi* for up to 4 days, from the specimens

stored at 4°C in a thioglycolate-hemin based medium containing L-glutamine and bovine albumin.<sup>48</sup> In swabs, *H. ducreyi* can survive for 2–4 hours only, and hence an alternative method (though less desirable) is to take the swab sample and place it in a transport media such as Amies.<sup>52–54</sup> Culture from intact buboes has even lower detection rates compared with culture from the ulcer base or culture from ruptured buboes.

### Culture Procedure

*H. ducreyi* grows best at 33°C in a microaerophilic, water saturated atmosphere containing 5% carbon dioxide, or in a traditional candle jar. Lenglet has been credited with the first successful *in vitro* culture of *H. ducreyi* in 1898.<sup>55</sup> Teague and Debert described the successful culture of *H. ducreyi* using fresh clotted rabbit blood heated to 55°C.<sup>56</sup> Numerous selective artificial media have been developed since. To date, the most widely used media are the gonococcal agar base enriched with 1% hemoglobin, 1% IsoVitalX, and 5% foetal calf serum; Mueller-Hinton agar enriched with 5% horse blood and 1% IsoVitalX; Columbia agar base with 5% lyzed horse blood, 2.5% yeast dialysate, and 1% IsoVitalX; enriched protease peptone agar; and heart infusion agar enriched with 10% foetal calf serum.<sup>34</sup> Nsanze et al. evaluated the potential benefit of using more than one medium to isolate *H. ducreyi* from clinical chancroid cases.<sup>57</sup> A simple inexpensive medium containing gonococcal agar base supplemented with 5% foetal calf serum and noncoagulated horse blood, and also a medium containing 0.2% activated charcoal instead of foetal calf serum, have been recommended for use in resource poor countries.<sup>58,59</sup> The success rate of *H. ducreyi* isolation in different culture media has been reported to range between 2% and 100%.

Cultures are incubated for 48 hours before noting the initial reading and kept for 5 days before reporting them negative. *H. ducreyi* exhibits an unusual tendency to autoagglutinate, when grown in a liquid medium or forms a cohesive colonial structure on agar plates. The colonies appear as nonmucoid, raised and granular, having a grayish-yellow color and can be pushed intact, across the surface of the agar with a bacteriologic loop. Gram staining of smears prepared from the colonies show gram-negative coccobacilli in short chains, clumps or whorls with individual bacterium showing bipolar staining. Identification can be done by  $\beta$ -lactamase production, oxidase test, nitrate reduction, requirement for hemin (X factor), and negative catalase, indole and urease tests.

### POLYMERASE CHAIN REACTION

Polymerase chain reaction (PCR) techniques have been developed to improve the sensitivity of diagnosis by DNA amplification<sup>60–66</sup> using primers based on the *H. ducreyi* 16S rRNA gene,<sup>60,63,65</sup> the *rrs* (16S)-*rrl* (23S) ribosomal intergenic spacer region,<sup>65</sup> an anonymous fragment of cloned *H. ducreyi* DNA,<sup>61</sup> the *groEL* gene,<sup>62</sup> or the 27 kDa *H. ducreyi*-specific protein (p27).<sup>66</sup> A multiplex PCR (M-PCR) assay has also been developed for the simultaneous amplification of DNA targets from *H. ducreyi*,

*Treponema pallidum*, and HSV types 1 and 2, and appears more sensitive than the standard diagnostic tests for the detection of these etiological agents in genital ulcer specimens.<sup>64</sup> Although PCR assays perform well with samples prepared from *H. ducreyi* cultures, they appear to be less sensitive when used to test genital ulcer specimens owing to the presence of Taq polymerase inhibitors in the DNA preparations extracted from the specimen.<sup>61</sup>

### ANTIGEN DETECTION BY IMMUNOFLUORESCENCE

Monoclonal antibodies (MAbs) have been raised against the 29 kDa outer membrane protein (OMP)<sup>67</sup> for direct immunofluorescence, and the MAb MAHD 7 against *H. ducreyi* lipooligosaccharide (LOS) for indirect immunofluorescence assays.<sup>68</sup> This assay can detect purified *H. ducreyi* LOS at a level of 25 pg/mL and could detect as few as 1000 CFU of *in vitro* grown *H. ducreyi*. The IF test identifies over 90% of the culture positive samples in addition to some culture negative chancroid cases. This technique has been shown to have a sensitivity of 100% and a specificity of 74% in comparison with culture, and a sensitivity of 81% in comparison with the PCR assay.

The immunolimus assay combines the specificity of a MAb raised against *H. ducreyi* LOS, and the sensitivity of the chromogenic limulus amebocyte lysate test for endotoxin.<sup>69</sup>

### ANTIBODY DETECTION BY SEROLOGICAL TESTS

Various serologic tests are available for the diagnosis of chancroid which include the enzyme immunoassays (EIAs), dot immunobinding, agglutination, complement fixation, and precipitation.<sup>70–72</sup> Antigens used for EIAs include the ultrasonicated whole cell antigen purified *H. ducreyi* LOS of OMPs.<sup>73</sup> None of these tests are commercially available at present. Though less sensitive to detect the circulating antibodies to *H. ducreyi* in individual patients having symptoms, these tests are helpful for screening in large scale epidemiological studies at the community level.<sup>74</sup>

Other tests include nucleic acid probe technology and mass spectrometric methods. *H. ducreyi* DNA can be detected by the technique of DNA-DNA hybridization using labeled *H. ducreyi*-derived probes. These probes are reliable and can detect 10<sup>4</sup> CFU of *H. ducreyi* in pure and mixed cultures. Also, oligonucleotides complementary to different regions in the 16S and 23S rRNA molecules of *H. ducreyi* have been synthesised.<sup>75</sup> Matrix assisted laser desorption-ionization time of flight mass spectrometry (MALDI-TOF MS) has been used for the rapid identification and speciation of *Haemophilus*.<sup>76</sup>

### HISTOPATHOLOGICAL EXAMINATION

The histological examination of the ulcer may be helpful in arriving at a diagnosis, even though the changes observed are not pathognomonic. The histopathologic picture consists of three zones: the *surface zone* at the floor is narrow and consists of neutrophils, fibrin, erythrocytes, and necrotic tissues; the

**Fig. 42.8:** Histology of chancroid ulcer showing dense infiltrate composed of mononuclear lymphocytes and plasma cells (H&E). Courtesy: Uma Nahar and Bishan D. Radotra, Chandigarh, India.

*middle zone* is wide, containing newly formed blood vessels showing marked proliferation of endothelial cells, thrombosis, and degenerative changes in the walls of the vessels; and the *deep zone* is composed of a dense infiltrate of plasma cells and lymphoid cells (Fig. 42.8).<sup>77</sup> Histological examination is useful to exclude malignancy in nonhealing or atypical ulcers.

### Differential Diagnosis

Chancroid has to be differentiated from other sexually transmitted GUDs, i.e., primary syphilis, genital herpes, granuloma inguinale, LGV and candidal balanitis, and non-STIs, such as traumatic ulcers, fixed drug eruption, and carcinoma. Coinfection of chancroid with *T. pallidum* or HSV may occur in up to 10% of patients.

### Antimicrobial Susceptibility

Recent reports from different parts of the world have revealed that clinically relevant antimicrobial resistance in chancroid has become common and is spreading rapidly.<sup>78–81</sup> More alarmingly, plasmid-mediated drug resistant strains of *H. ducreyi* to ampicillin, sulfonamides, chloramphenicol, tetracycline, streptomycin, and kanamycin have been reported.<sup>34</sup> However, these strains are extremely sensitive to several other antibiotics, especially the macrolides (erythromycin and azithromycin), the quinolones (ciprofloxacin and fleroxacin), and the third-generation cephalosporins (ceftriaxone, cefotaxime, and cefixime).<sup>33</sup>

## Treatment

Chancroid is an important cofactor in facilitating the transmission of HIV infection.<sup>1</sup> Prompt and adequate therapy of affected patients and their contacts is vital, in addition to the aggressive implementation of appropriate control and prevention measures for eradicating the disease.

Earlier treatments, such as sulfonamides, ampicillin, tetracyclines, and streptomycin, are no longer being recommended because of poor response rates and widespread resistance developed by *H. ducreyi* to these antimicrobials. Trimethoprim-sulfamethoxazole has been used extensively for chancroid in the past; however, resistance to this drug has now been noted in many parts of the world (Thailand, Kenya, and Rwanda). Erythromycin is effective in a dose of 500 mg 4 times a day, orally for 7 days.<sup>82</sup> Studies indicate that single-dose treatment with spectinomycin or ceftriaxone are also quite effective in the treatment of chancroid.<sup>80,83</sup> Azithromycin 1 g single-dose is highly effective but quite expensive. Fluoroquinolones, especially ciprofloxacin 500 mg given as single-dose orally has been found to be safe, convenient, and effective in chancroid; however, treatment failures have occurred in patients with concomitant HIV infection.

Current therapies recommended for chancroid are summarized in Table 42.2, and the treatment guidelines can be accessed at:

1. WHO: <http://apps.who.int/medicinedocs/en/d/Jh2942e/4.5.html#Jh2942e.4.5>

2. CDC: <http://www.cdc.gov/std/treatment/2006/genital-ulcers.htm#genulc2>
3. CEG/BASHH: <http://www.bashh.org/guidelines>

## SPECIAL CONSIDERATIONS

The safety of azithromycin in pregnant and lactating women has not been established. Ciprofloxacin is contraindicated in pregnancy, lactating women, children, and adolescents less than 18 years of age, hence erythromycin or ceftriaxone regimens should be used. No adverse effects of chancroid on pregnancy outcome or on the foetus have been reported. If associated with HIV infection, the patients have to be closely monitored. Healing of ulcers may be slower among HIV infected people and treatment failures have been reported with azithromycin, ceftriaxone, single-dose fleroxacin, low-dose erythromycin or ciprofloxacin. However, some recent studies have not shown any increased treatment failures in HIV-positive cases with low-dose erythromycin and single-dose ciprofloxacin. Currently, the data on therapeutic efficacy with the recommended ceftriaxone and azithromycin regimens among patients infected with HIV is limited. Hence, CDC recommends that these regimens should be used among persons known to be infected with HIV, only if a proper follow-up can be assured. However, some experts advocate the use of full doses of erythromycin for 7 days for treating HIV-infected persons.

**Table 42.2:** Comparative Analysis of the Current *Standard* Therapies Recommended for Chancroid by the World Health Organization (WHO 2003), the National Aids Control Organization (NACO, India 2005), the Centers for Disease Control (CDC, USA 2006), and the BASHH Clinical Effectiveness Group (CEG, UK 2007)

Drug	Dose	Dosing interval	Duration	Route	Recommending organization			
Erythromycin base	500 mg	QID	7 days	Oral	WHO	NACO	-	CEG
Erythromycin base	500 mg	TID	7 days	Oral	-	-	CDC	-
Erythromycin stearate	500 mg	QID	7 days	Oral	-	NACO	-	-
Erythromycin ethyl succinate	800 mg	QID	7 days	Oral	-	NACO	-	-
Azithromycin	1 g	Single-dose	-	Oral	WHO	NACO	CDC	CEG
Ceftriaxone	250 mg	Single-dose	-	Intra-muscular	-	NACO	CDC	CEG
Ciprofloxacin	500 mg	BD	3 days	Oral	WHO	-	CDC	CEG
Ciprofloxacin	500 mg	BD	3–5 days	Oral	-	NACO	-	-
Ciprofloxacin	500 mg	Single-dose	-	Oral	-	-	-	CEG
Doxycycline	100 mg	BD	7 days	Oral	-	NACO	-	-
Trimethoprim-Sulfamethoxazole	TMP (80 mg)-SMX (400 mg)	2 tabs BD	2 weeks	Oral	-	NACO	-	-

Although not yet commercialized for human use, a promising potential vaccine technology has been developed. In this scenario, high-risk individuals in endemic areas could undergo vaccination against a heme-receptor essential for *H. ducreyi* survival in skin. Antibodies arising after this vaccination have prevented infection *in vivo* in a porcine model of chancroid.<sup>84</sup>

## MANAGEMENT OF ULCERS AND FLUCTUANT BUBOES

Bed rest is recommended early in the course of disease because of pain. Local antiseptics are contraindicated as they would interfere with the diagnosis of concomitant syphilis by dark-ground microscopy. Local cleansing with normal saline is advocated. Fluctuant buboes can be aspirated with a needle from the adjacent healthy skin, and should not normally be incised as there is a risk of autoinoculation. Although incision and drainage of fluctuant buboes under antibiotic cover has been recommended in the past,<sup>82</sup> it is contraindicated according to the latest recommendations from WHO.

## FOLLOW-UP

Re-examination of the patient should be carried out on the seventh day after initiation of therapy. With the administration of proper treatment, the ulcers should show improvement symptomatically in 3 days followed by substantial re-epithelialization after 7 days. The time required for complete healing is related to the size of the ulcer and possibly the HIV status of the individual; large ulcers may require more than 2 weeks. Also healing is slower for some uncircumcised men who have an ulcer under the foreskin. Resolution of lymphadenopathy is slower than that of the ulcer.

## TREATMENT FAILURE

Coinfections with *T. pallidum* or HSV may result in partial or no improvement. During the past decade, high-level, plasmid-mediated drug resistance to sulfonamides, penicillins, kanamycin, streptomycin, tetracycline, chloramphenicol, and trimethoprim has been observed in *H. ducreyi* isolates. The most suitable medium to determine minimum inhibitory concentrations (MIC) is the Mueller-Hinton agar enriched with 1% hemoglobin, 5% foetal calf serum, and 1% HD supplement. Alternatively, a gonococcal agar base can be used.<sup>34</sup> If drug resistance is suspected, it is important to do antimicrobial drug susceptibility testing of *H. ducreyi* by the agar dilution technique<sup>85</sup> or the equally effective but simpler E-test.<sup>86</sup>

## MANAGEMENT OF SEXUAL PARTNER(S)

Sexual contacts within the last 10 days before the onset of patient's symptoms should be examined and treated, even in the absence of symptoms, in view of possible asymptomatic carriage.<sup>25</sup> Serological tests for syphilis and HIV should be offered to all patients and their contacts.

## Syndromic Approach

The clinical differentiation of chancroid from other GUDs is not reliable and culture of *H. ducreyi* is not routinely available, thereby imposing constraints on diagnosis, treatment, and control strategies.<sup>1</sup> Several studies have established that GUDs facilitate the risk of acquisition and transmission of HIV infection.<sup>87</sup> Hence, the current syndromic approach for the treatment of STIs, proposed by WHO is essential to manage GUDs and prevent HIV infection, especially in resource-poor nations where chancroid is endemic.<sup>88–91</sup>

## HIV and Chancroid

Chancroid facilitates the transmission of HIV by increasing both the infectiousness of HIV and the susceptibility to infection by the virus. Subjects with HIV infection and a concomitant chancroid ulcer demonstrate increased infectiousness through the following:

1. There is increased HIV shedding into the genital tract from ulcer exudates. In Cote d'Ivoire, HIV-positive female sex workers with cervicovaginal ulcers had higher rates of HIV isolation from cervicovaginal lavage fluids than those without ulcer disease (66.8% vs. 21%). Adjustment for the level of immunosuppression did not alter these findings. Treatment of the chancroid ulcer reduced HIV detection to levels similar to those of individuals without GUD.
2. Genital ulcers bleed during intercourse, resulting in potential increases in viral shedding and HIV infectiousness.
3. In men with GUD, there is increased concentration of the virus in seminal fluid, especially in those who also have nongonococcal urethritis. This is attributed to an increased plasma viral load from advanced disease or systemic immune activation by *H. ducreyi*.<sup>38</sup>

GUD, particularly chancroid, has been shown to increase the risk of acquiring HIV infection.<sup>17,92–94</sup> Genital ulcers provide a portal of entry for both HIV-1 and HIV-2. *H. ducreyi* infection recruits CD4+ lymphocytes and macrophages to genital surfaces and these cells are the principal early targets for HIV infection. Concomitant HIV infection may alter the clinical presentation of chancroid lesions. The ulcers may present with atypical features, such as large size and number, and extragenital location. The ulcers may take a longer time to heal. HIV appears to reduce the responsiveness of chancroid to standard therapy, especially single-dose regimens, possibly requiring treatment for a longer period and/or increased dosing.<sup>84</sup>

## Prevention and Control

*H. ducreyi* survives largely in networks with a high rate of sexual partner change, including MSM and CSWs. Control policies targeting these high risk groups will result in the rapid disappearance of chancroid from a community. Once endemic in Europe and North America, the incidence of chancroid declined steadily

early in the twentieth century. Greater awareness and changes in the pattern of commercial sex probably disrupted the conditions necessary to sustain chancroid as an endemic disease among these communities.<sup>1</sup> Several antibiotics, including some single-dose regimens, have the advantage of providing a rapid cure as well as ease of administration. Sporadic outbreaks can be controlled with effective treatment and preventive services targeted at high risk groups. More recently, the prevalence of chancroid has decreased in Thailand, Philippines, and Senegal with the implementation of intervention strategies targeting CSWs and their clients, a development that may contribute to the reduction of STIs and the stabilization of the HIV epidemic in these countries.

Greater awareness regarding diagnosis and treatment, strengthening diagnosis and treatment of STIs, widespread promotion of condom use, contact tracing, a targeted approach towards high risk groups, emphasis on maintaining local hygiene, and the use of a syndromic approach can all go a long way towards bringing down the incidence of this disease.

## Introduction

Donovanosis is a progressive, mildly infectious bacterial infection that usually involves the genital area. The causative organism is a gram-negative bacillus, *Calymmatobacterium granulomatis*. A proposal that the organism be reclassified as *Klebsiella granulomatis* *comb nov* has been put forward.<sup>1</sup>

## History and Terminology

Donovanosis has been known under many different terminologies and this has undoubtedly led to confusion with lymphogranuloma venereum. The terms used most commonly are donovanosis and granuloma inguinale. This author, along with Marmell and Santora believes that donovanosis is the most appropriate term.<sup>2</sup>

Other terminologies used for donovanosis include the following:<sup>3</sup>

- Granuloma inguinale
- Granuloma venereum
- Lymphogranuloma inguinale
- Granuloma genito-inguinale
- Granuloma contagiosa
- Granuloma donovani
- Granuloma inguinale tropicum
- Ulcerating granuloma of the pudenda
- Infective granuloma
- Chronic venereal sores
- Ulcerating sclerosing granuloma
- Granuloma venereum genito-inguinale

Macleod, Professor of Surgery in Calcutta and originally from Scotland, first described donovanosis in 1882.<sup>4</sup> He reported cases of serpiginous ulceration in men and genital elephantiasis in a woman. Further cases were reported in British Guinea and the UK.<sup>5,6</sup>

The causative organism was first described by Charles Donovan in 1905.<sup>7</sup> Donovan (Fig. 43.1) was born in Calcutta, graduated from Cork University and the Royal University of Ireland and then entered the Indian Medical service.<sup>8</sup> While working in Madras, he identified the characteristic Donovan bodies measuring  $1.5 \times 0.7 \mu\text{m}$  in macrophages and epithelial cells of the stratum malpighii.

**Fig. 43.1:** Lieutenant-Colonel Charles Donovan.

Culture of the organism proved to be difficult. Aragao and Vianna claimed to have cultured the organism from ulcer lesions and identified it as *C. granulomatis*.<sup>9</sup> Further attempts at culture were unconvincing until 1943 when Anderson isolated the organism.<sup>10</sup> Earlier, Pund and Greenblatt described pathognomonic cells, the so-called Pund cells in 1937.<sup>11</sup> These consisted of large mononuclear cells 25–90  $\mu\text{m}$  in diameter filled with intracytoplasmic cysts with deep-stained bodies.

In 1951, Rajam and Rangiah, working in Madras, published a comprehensive WHO monograph based on their experience of having examined and treated nearly 2000 cases over 20 years.<sup>3</sup> From the mid 1960s, reports of the condition were limited until the late 1980s/early 1990s when the association between genital ulceration and HIV was identified and led to renewed interest in the condition. There followed increased efforts to tackle genital ulcers as a public health issue. In addition, syndromic management algorithms for genital ulcers were implemented more effectively along with the recommendation that cases be followed-up until

complete healing was achieved. Subsequently, the incidence of donovanosis decreased to the extent that cases are now almost sporadic even in areas where the condition was once prevalent in significant numbers.

## Biology

The causative organism is an intracellular, gram-negative pleomorphic bacterium identified as the Donovan body. Goldzieher and Peck<sup>12</sup> identified Donovan bodies in histological tissue sections in 1926 and described a large mononuclear cell containing the specific organisms. Pund and Greenblatt used Delafield hematoxylin and eosin and Dieterle silver impregnation methods to describe this characteristic cell filled with intracytoplasmic cysts that eventually rupture with the release of infective organisms.<sup>11</sup> Sehgal described gram-negative intra- and extra-cellular Donovan bodies with different morphologic features consisting of coccoid, coccobacillary, and bacillary forms.<sup>13</sup>

Electron microscopy studies have shown organisms with gram-negative morphology and a large capsule but no flagella (Fig. 43.2).<sup>14</sup> Filiform protrusions may be seen on a corrugated cell wall<sup>15</sup> but other surface structures are not found.<sup>16</sup> Early on, the causative organism was noted to possess marked similarities to *Klebsiella* species.<sup>17</sup> More recently, polymerase chain reaction (PCR) tests were developed in Darwin and Durban and further molecular characterization of the causative organism was undertaken.<sup>1,18–20</sup> DNA sequencing of the 16S rRNA and *phoE* genes demonstrated that *C. granulomatis* had a greater than 99% similarity with *K. pneumoniae* and *K. rhinoscleromatis*. Carter et al. proposed that the causative organism be reclassified as *K. granulomatis comb nov* and set out an amended description of the genus *Klebsiella* to include donovanosis.<sup>1</sup> However, Kharsany et al. performed a phylogenetic analysis of *C. granulomatis* based on 16S rRNA gene sequences and found that strains had similarities of only 95% and 94%, respectively, to the genera *Klebsiella* and *Enterobacter*.<sup>20</sup> They concluded that *C. granulomatis* was a unique species belonging to the subclass of *Proteobacteria* and distinct from other related organisms. Differences in these results have not been explained, and resolution of the conflict regarding classification has not yet been achieved.

## Epidemiology

In the preantibiotic era donovanosis was prevalent in many diverse geographic locations. Rajam and Rangiah stated that the disease was distributed in both hemispheres and endemic in southern China, the East Indies, northern Australia, West and central Africa, some countries of Central, South, and North America, and the West Indies.<sup>3</sup> In the United States, Greenblatt estimated a population prevalence of 5,000–10,000 cases in 1947.<sup>21</sup> Nowadays significant numbers are found in only a few developing countries and these are decreasing year by year. Sporadic cases do occur in developed countries and are often the subject of case reports. A small epidemic of 20 cases was reported in 1984 in the US.<sup>22</sup>

The main foci of donovanosis in recent times have been in Papua New Guinea,<sup>23</sup> southern Africa, particularly the Durban-KwaZulu-Natal region,<sup>24</sup> and eastern Transvaal.<sup>25</sup> Elsewhere, significant numbers of cases have been reported from Zimbabwe<sup>26</sup>, parts of India,<sup>27</sup> northeast Brazil<sup>28</sup>, French Guyana,<sup>29</sup> and aboriginal communities in Australia.<sup>30</sup> Papua New Guinea seems to have been the worst affected region; in 1980 donovanosis accounted for 46% of genital ulcers in women.<sup>31</sup> In a study at five health centers in 1989/90, donovanosis was the second most common cause of genital ulceration after genital herpes<sup>32</sup> and the most common sexually transmitted infection (STI) among new STI attendees in Porgera Enga province in 1992/3.<sup>33</sup> However, a more recent WHO consensus report states that donovanosis has now become rare in Papua New Guinea.<sup>34</sup> The largest epidemic recorded was in Dutch South New Guinea between 1922 and 1952, when 10,000 cases were reported from a population of 15,000.<sup>35</sup>

In the main STI clinic in Durban, South Africa, following a decrease after a peak in 1969–74,<sup>23</sup> the numbers of donovanosis cases recorded in the annual reports of the medical officer increased from 312 in 1988 to 3153 in 1997.<sup>24,36</sup> In a microbiologic study of genital ulcer disease among STI clinic attenders in Durban, donovanosis was diagnosed in 11% of men<sup>37</sup> and 16% of women in 1988.<sup>38</sup> Although genital ulcer diagnoses in Durban were recorded syndromically without mention of likely specific etiologies after 1997, it would appear that donovanosis has now decreased significantly. Recent genital ulcer surveys in men identified donovanosis in 4% in 1999<sup>39</sup> with a further reduction to less than or equal to 1% in 2001<sup>40</sup> and 2004.<sup>41</sup> Prior to the 1980s, it was reported that few cases were present in South Africa and the suggestion made that donovanosis had all but disappeared.<sup>42</sup> A more likely explanation is that there were few individuals with any interest in STDs in South Africa at that time so that the condition attracted little interest and went unrecognized or was diagnosed as lymphogranuloma venereum.<sup>43</sup> Elsewhere in Africa sporadic cases of donovanosis have been reported in recent times from Botswana,<sup>44</sup> the Central African Republic<sup>45</sup> Gabon<sup>46</sup>, and Zambia.<sup>47</sup>

In India, donovanosis was prevalent mainly in the states of Madras and Orissa in the south and Himachal Pradesh in the north with the greatest incidence along the eastern seaboard.<sup>3</sup> Between 1993 and 1997<sup>48</sup> donovanosis accounted for 14%

of genital ulcer cases at a southern STI clinic, 15% of whom were HIV positive but in North India the number of cases dropped considerably in the 1990s<sup>49</sup>. In Jamaica, the prevalence of donovanosis diagnosed on clinical grounds decreased from 4.1% in 1982/3 to 2.3% in 1990/1.<sup>50</sup>

In Australia a donovanosis elimination program was launched in 1998 among Aborigines.<sup>51,52</sup> This involved designated clinical officers who coordinated clinical protocols, performed health-promotion activities, validated epidemiological data, ensured laboratory control, and assisted in the follow-up of hard to reach cases. This program has achieved remarkable success and reduced the number of annual cases to a handful throughout Australia.<sup>53</sup>

It has been questioned as to whether donovanosis is sexually transmitted because of the low incidence of the disease, the differences in the racial and sex distributions, uncertainty about the incubation period, infrequency of cases of conjugal infection, and the occurrence of primary extragenital lesions.<sup>54</sup> The condition undoubtedly has several unusual epidemiologic features that warrant further scrutiny.

The majority of cases are in the 20- to 40-year age group, that is, the most sexually active. Most case series have recorded a preponderance of males, although in some studies with limited numbers of cases, such as in Zambia,<sup>47</sup> western Australia,<sup>55</sup> and eastern Transvaal, South Africa,<sup>56</sup> more women than men have been reported. Rajam and Rangiah<sup>3</sup> recorded 1350 men and 562 women in their large series, and similar male-to-female ratios have been reported in Zimbabwe<sup>26</sup> and southeast India.<sup>57</sup> Higher male-to-female ratios of more than 6:1 have been reported from Papua New Guinea<sup>23</sup> and India.<sup>58</sup>

The incubation period is uncertain. Sehgal and Prasad<sup>59</sup> found the average incubation period to be 17 days, but a range of 1–360 days has been reported.<sup>60</sup> Experimental production of typical donovanosis lesions was induced in humans 50 days after inoculation.<sup>61</sup>

Among sexual partners of index cases, wide variations in the rates of infection have been reported. In Papua New Guinea<sup>23</sup> and the US<sup>62</sup> the coinfection rate was 1–2%, whereas in India rates of up to 50% were reported among marital partners examined.<sup>57,63</sup> A more recent study of 255 cases in India in which eight couples were examined found conjugal involvement in one pair only.<sup>64</sup> In many cases the disease is mild, particularly in men, and examination of all regular sexual partners is recommended.

Transmission via fecal contamination of abraded skin was suggested as a possible mode of transmission by Goldberg.<sup>65</sup> Although he isolated the causative organism from feces, there are no subsequent reports to support this hypothesis. Cases in children have been attributed to sitting on the laps of infected adults.<sup>66</sup> Disseminated donovanosis has been reported in a neonate born to a mother with a large granulomatous lesion of the vulva who incurred a third-degree tear during delivery.<sup>67</sup>

## Immunology

McIntosh first described antibody production against the organism and he achieved experimental transmission of the

organism from one individual to another.<sup>68</sup> Skin testing was tried but found to have poor sensitivity.<sup>69–71</sup>

No serologic tests are currently in generalized use. Complement-fixation tests were developed and found to be reasonably sensitive<sup>69–72</sup> but had a poor specificity. Positive immunofluorescence and immunoperoxidase reactions have been identified in tissue sections from donovanosis lesions after incubation with sera from patients with donovanosis.<sup>73</sup>

An indirect immunofluorescent technique using sections from proven donovanosis lesions as antigens had a high sensitivity for established lesions but was not deemed suitable for early donovanosis ulcers. However, this test could be of use as an epidemiologic tool in population studies.<sup>74</sup> A study of lymphocyte sub-populations showed an increase in B lymphocyte and immunoglobulin levels but no further work has been done in this area.<sup>75</sup> In Durban, HLA studies showed an association between donovanosis and HLA-B57 and a trend toward resistance to disease with HLA-A23.<sup>76</sup>

## Clinical Features

The first sign of infection is usually a firm papule or subcutaneous nodule that later ulcerates. Four types of donovanosis are described classically: (i) Ulcerogranulomatous—the most common variant—non-tender, fleshy, exuberant, single or multiple, beefy-red ulcers that bleed readily when touched (Figs. 43.3–43.5); lesions spread by direct extension and autoinoculation. (ii) Hypertrophic (Fig. 43.6) or verrucous type—an ulcer or growth with a raised, irregular edge, sometimes completely dry with a walnut-like appearance. (iii) Necrotic, usually a deep, foul-smelling ulcer causing tissue destruction. (iv) Sclerotic or cicatricial, characterized by extensive formation of fibrous and scar tissue; this variant usually requires histological examination to confirm the diagnosis.

The genitals are affected in 90% of cases and the inguinal region in 10%. The usual sites of infection are, in men, the prepuce, coronal sulcus, frenum, and glans penis and, in women, the labia minora and fourchette. A preponderance of cases has long been recognized in uncircumcised men.<sup>77</sup> Lesions of the cervix may mimic cervical carcinoma. Extragenital lesions occur

**Fig. 43.3:** Typical subpreputial ulcerogranulomatous donovanosis lesions.

Fig. 43.4: Penile donovanosis lesions.

Fig. 43.5: Confluent donovanosis lesions at fourchette.

Fig. 43.6: Inguinal hypertrophic lesions of donovanosis.

in 6% of cases but are often missed in non-endemic areas.<sup>3,78,79</sup> Sites of infection include the lip, gums, cheek, palate, pharynx, neck, nose, larynx, and chest. Extragenital lesions are usually associated with primary genital disease. On the rare occasions when primary extragenital lesions are diagnosed, the possibility of rhinoscleroma should be considered. Rhinoscleroma is caused by *K. rhinoscleromatis* and is an organism closely related to the causative organism of donovanosis.

Lymphadenitis is an uncommon finding.<sup>80</sup> Disseminated donovanosis is rare, but secondary spread to liver and bone may occur and is usually associated with pregnancy and cervical lesions. Polyarthrititis and osteomyelitis are rare complications.<sup>81</sup>

## Complications and Sequelae

Rajam and Rangiah found carcinoma, either as a complication of or a sequel to long-standing donovanosis, to be a rare occurrence, seen in 0.25% of 2000 cases.<sup>3</sup> Positive reactivity with *C. granulomatis* antigens was found in 9 of 62 cases of carcinoma of the penis in Jamaica, but this work was not developed further.<sup>82</sup>

Nowadays, the most frequent complication is pseudoelephantiasis, which is more common in women and found in up to 5% of cases.<sup>83</sup> Surgical intervention may be required for advanced intractable lesions.<sup>84</sup> Stenosis of the urethra, vagina, or anus may occur in the sclerotic variant of donovanosis.<sup>3</sup>

The differential diagnosis between donovanosis and squamous cell carcinoma of the penis may be difficult.

Donovanosis ulcers may be coinfecting with other STIs, particularly syphilis.<sup>31,37</sup> Such cases justify management by the syndromic approach with treatment for both conditions. However, it is important that these patients be followed, even when managed by primary healthcare workers, until complete healing is achieved. The presence of donovanosis ulcers does not preclude sexual intercourse,<sup>85</sup> and the risks of reinfection should be stressed at the initial consultation.

## Pregnancy and Donovanosis

Donovanosis has a more aggressive course during pregnancy and lesions may increase in size rapidly.<sup>77,86,87</sup> Neonatal cases may present with ear infections following transmission from an infected mother.<sup>88,89</sup> Children born to mothers with untreated donovanosis should receive antibiotic prophylaxis. Careful cleansing of neonates born to infected mothers is recommended.<sup>88</sup>

## Donovanosis and HIV

The classic STIs, and genital ulcer diseases in particular, are significant risk factors for HIV in developing countries. In Durban, in a population where HIV infection had been introduced only recently, the proportion of men with donovanosis and HIV infection increased significantly as the duration of lesions increased, thereby suggesting that HIV was acquired via sexual intercourse in the presence of ulcers.<sup>90</sup>

The treatment of donovanosis may need to be modified in HIV-infected patients with significant immunosuppression. In Mumbai, India, the mean healing time in HIV-positive patients with donovanosis was 25.7 days compared to 16.8 days in HIV-negative subjects.<sup>27</sup> In Brazil, two AIDS patients with donovanosis failed to respond to conventional treatment with combinations of cotrimoxazole, tetracycline, and thiamphenicol.<sup>91</sup> Interestingly, two HIV-positive patients with oropharyngeal infections with *K. rhinoscleromatis* required prolonged courses of antibiotics before clinical cure.<sup>92</sup> However, among HIV-positive pregnant women without significant documented immunosuppression, the clinical presentation and response to treatment in donovanosis appeared to be unaltered by HIV.<sup>93</sup> Further clarification of the role of oral azithromycin in the management of donovanosis in HIV-positive

patients is awaited. Other complications of donovanosis are uncommon in HIV-infected individuals, although one case of co-existent squamous cell carcinoma is reported.<sup>94</sup>

## Diagnosis

### DIFFERENTIAL DIAGNOSIS

Ulcerogranulomatous donovanosis lesions have a characteristic appearance and should be distinguished readily from the other classic STI causes of genital ulcer disease.<sup>95</sup> However, primary syphilitic chancres, secondary syphilis (condylomata lata), chancroid, and large herpetic ulcers can all be mistaken for donovanosis. Amoebiasis and carcinoma of the penis should also be considered if tissue destruction or necrosis is present. In developed countries, a history of travel and sex in an endemic country may lead to a diagnosis of donovanosis.<sup>96</sup>

### TISSUE SMEARS

Direct microscopy of tissue smears is the mainstay method of diagnosis. Confirmatory specimens can usually be obtained as long as an adequate smear is prepared and antibiotic treatment has not been started. Most centers with experience with donovanosis have developed their own methods for maximizing the diagnostic yield from clinical specimens. Greenblatt and Barfield<sup>97</sup> advocated obtaining crush biopsy samples from the edges of lesions and stressed the importance of obtaining clean specimens for the preparation of tissue smears. Rajam and Rangiah<sup>3</sup> obtained material by means of a curette, forceps, the sharp end of a broken slide, or the edge of a safety razor blade and crushed the specimen between two slides and stained by the Leishman or Giemsa methods. Rapid results have been achieved using material obtained with a chalazion spoon.<sup>98</sup> Other stains used include Delafield hematoxylin and eosin,<sup>11</sup> Wright,<sup>99</sup> and pinacyanole.<sup>100</sup> A 100% success rate was claimed using a slow-Giemsa (overnight) technique.<sup>101</sup> A modified Giemsa stain (RapiDiff) has yielded rapid results in a busy clinic environment<sup>102</sup> (Figs. 43.7, 47.8). The organisms are pleomorphic and are usually ovoid or bean-shaped. The capsule is pink and the body of the organism is bluish/purple. Giemsa staining may show bipolar inclusions and often have a safety-pin appearance. Organisms stained with RapiDiff have a more homogeneous picture. Organisms may occur in clusters

**Fig. 43.7:** Tissue smear stained by rapid Giemsa (RapiDiff) technique showing numerous Donovan bodies in large monocyte (Pund cell).

**Fig. 43.8:** Tissue smear stained by RapiDiff showing Donovan bodies in small cysts.

or in small cysts inside the mononuclear cell. Donovan bodies have also been identified in Papanicolaou smears.<sup>103</sup> If multiple swabs are taken from ulcers and donovanosis is considered likely, the smear for Donovan bodies should be taken first so that an adequate amount of material can be obtained from the ulcer.

### HISTOPATHOLOGY

Biopsy and histologic examination may be required for lesions that are small, dry, sclerotic, or necrotic. Giemsa or silver stains are the most effective methods for visualizing the organisms in tissue sections. The characteristic histologic picture shows chronic inflammation with infiltration of plasma cells and polymorphonuclear leukocytes (Fig. 43.9)<sup>12</sup>; the dermis shows a dense cellular infiltrate with large numbers of plasma or Pund cells. Ulceration and acanthosis with focal collections of polymorphonuclear leukocytes are found in the epidermis; elongation of rete ridges occurs in association with the hypertrophic variant.<sup>13</sup>

**Fig 43.9:** Histology of donovanosis showing ulcerated epidermis, pseudoepitheliomatous hyperplasia and dense infiltrate in dermis, primarily of plasma and mononuclear cells (H&E, x 550). *Courtesy:* Uma Nahar and Bishan D. Radotra, Chandigarh, India.

## CULTURE

After Aragao and Vianna's initial publication,<sup>9</sup> Cornwall and Peck cultured an organism that when injected into rabbits produced granulomatous lesions simulating donovanosis at the site of injection.<sup>104</sup> DeMonbreun and Goodpasture<sup>105</sup> grew gram-negative bacilli of the *Aerogenes* group from ulcers and feces of patients with donovanosis in a filtrate of chick membrane in both the capsulated and non-capsulated forms. Greenblatt et al.<sup>61</sup> were able to transmit the disease into human volunteers by introducing material from a pseudobubo but failed to grow the organism on the chorioallantois of chick embryos.<sup>106</sup>

Attempts at culture remained unconvincing until 1943 when Anderson<sup>10</sup> reported the isolation of the causative organism on the yolk sac of chick embryos and proposed a new genus, *Donovania*, and species, *granulomatis*.<sup>107</sup> Further efforts to develop an artificial medium for the culture of *D. granulomatis* met with only limited success. Some growth was achieved by Dunham and Rake using beef heart infusion agar and normal chick embryo yolk sacs with subsequent transfer to tryptose beef heart infusion broth and modified Levinthal stock broth.<sup>69</sup> Positive skin reactions were demonstrated in human subjects with donovanosis after injection of bacterial antigen prepared from infected yolk sacs.<sup>72</sup> It would now seem that some of the earlier claims of successful cultures may have been due to contamination.

After 1962,<sup>65</sup> there were no reports of successful culture until 1996/7 in Durban,<sup>108,109</sup> where the causative organism was shown to multiply in a monocyte co-culture system from biopsy specimens after pretreatment with amikacin. In Darwin, the organism was grown using a modified chlamydia culture system with human epithelial cell lines.<sup>110</sup>

## MOLECULAR METHODS

In Darwin amplification of Klebsiella-like sequences was achieved using primers targeting the *phoE* gene. A diagnostic PCR was produced using the observation that two unique base changes in the *phoE* gene eliminate HaeIII restriction sites enabling clear differentiation from closely related species of Klebsiella.<sup>18,19</sup> A colorimetric PCR detection system can now be used in routine diagnostic laboratories.<sup>111</sup> A genital ulcer multiplex PCR that includes *C. granulomatis* in addition to herpes simplex viruses, *Haemophilus ducreyi*, and *Treponema pallidum* has been developed.<sup>112</sup> The presence of *C. granulomatis* was confirmed by restriction enzyme digestion and nucleotide sequencing of the 16rRNA gene for phylogenetic analysis.

## Management

### MEDICAL TREATMENT

Donovanosis is one of the few bacterial infections that could be treated in the preantibiotic era. Antimony compounds were used successfully for primary infections but had limited efficacy for recurrences or reinfections.

The first antibiotic shown to be effective for donovanosis was streptomycin in 1947.<sup>113</sup> Nowadays, various therapeutic treatments are used and probably reflect local availability of different drugs. Streptomycin has been used extensively in India and is effective for large lesions, although daily injections are required.<sup>114</sup> Chloramphenicol has been used in Papua New Guinea,<sup>115</sup> cotrimoxazole in India<sup>116</sup> and South Africa,<sup>117</sup> and thiamphenicol in Brazil.<sup>118</sup> Healing is usually achieved with tetracycline, although resistance is reported.<sup>119</sup> Norfloxacin,<sup>120</sup> ciprofloxacin,<sup>121</sup> and high-dose ceftriaxone<sup>122</sup> are also effective. Gentamicin 1 mg/kg three times daily intramuscularly or intravenously can be given if there is no response in the first few days with other regimens. Erythromycin is recommended during pregnancy. Encouraging results have been shown with azithromycin which has now become the drug of choice; a course of 500 mg daily for 1 week or 1 gram weekly for 4–6 weeks are both effective<sup>123</sup>; WHO recommends 1 gram followed by 500 mg daily,<sup>124</sup> and the Centers for Disease Control and Prevention recommends 1 gram weekly for at least three weeks until lesions are healed.<sup>125</sup> Expanded access to azithromycin would be a major step forward and contribute significantly to limiting compliance problems with other therapies currently in use.

Children with donovanosis should receive a short course of azithromycin 20 mg/kg. Children born to mothers with untreated donovanosis should receive prophylaxis with a three-day course of azithromycin 20 mg/kg once daily.<sup>88</sup>

## INFORMATION, EDUCATION, AND COUNSELING

Poor understanding has in the past led patients with severe donovanosis to become shunned and ostracised.<sup>3</sup> Many sufferers express profound feelings of shame, guilt, and embarrassment. Some have resorted to suicide. Even now, extreme rejection is not unusual.<sup>126</sup>

In many developing countries, donovanosis patients are seen at STI clinics after attending primary healthcare centers where various treatment approaches have failed. Patients with large lesions of donovanosis may need prolonged courses of antibiotics and require careful explanation and reassurance about a condition that they may have had for a long time. Where possible, this is probably best given by staff that have chosen to work with STI patients and can give individual attention coupled with a sympathetic, non-judgmental approach.<sup>127</sup> Clearly, there is a need for on-going education of healthcare workers about donovanosis in endemic areas and to raise community awareness of the importance of genital ulcer disease as a proven risk factor for HIV transmission.<sup>128</sup>

## Prevention and Control

Donovanosis is one of the most easily recognizable causes of genital ulcer disease clinically in endemic areas.<sup>95</sup> Because it is limited to a few specific geographic locations, local elimination and even global eradication are realistic objectives<sup>53,129</sup> that are justified if the high proportion of HIV transmissions attributable to genital ulcers is taken into consideration.<sup>130</sup> Such programs would need to appreciate the diverse nature of the communities affected and include careful appraisal of local customs and beliefs.

Although communities in the donovanosis-endemic countries of Papua New Guinea, India, South Africa, Brazil, and Australia differ markedly, they all have similarities that may be relevant to donovanosis control. Most individuals with donovanosis in these communities are subject to social deprivation, low socioeconomic status, and poor standards of personal genital hygiene.

Donovanosis should remain high on the list of differential diagnoses of genital ulceration in female sex workers in donovanosis-endemic countries. In India,<sup>3</sup> USA,<sup>22</sup> and Papua New Guinea,<sup>23</sup> prostitutes have been identified as source contacts of index cases and usually have clinically detectable lesions. In Papua New Guinea, local sexual practices and beliefs may play a significant role in the spread of donovanosis: It is not unknown for many men to have sexual intercourse with a single woman during festival occasions<sup>131</sup>; furthermore, some men believe that impurities in their blood cause donovanosis ulcers and resort to self-mutilation in an attempt to “release” the cause of the problem.<sup>132</sup> It should also be noted that Papua New Guinea has the highest prevalence of HIV in the Oceania region.<sup>133</sup>

Since the overall prevalence of donovanosis in most endemic areas is low, mass surveys to identify cases or mass treatment campaigns are not justified. However, mass treatment of cases identified in house-to-house visits in Goilala, Papua New Guinea, was successful in controlling a localized epidemic in the 1950s.<sup>66</sup>

Global eradication of donovanosis remains a possibility but will require significant input and leadership from the WHO if it is to be placed on the disease-eradication agenda.

### Summary

Donovanosis is a cause of genital ulceration found mainly in a limited number of developing countries. Sporadic case may occur elsewhere. The causative organism is *Calymmatobacterium granulomatis* although a proposal has been put forward to reclassify it as *Klebsiella granulomatis*. The classical ulcerogranulomatous lesion is a beefy, red ulcer that bleeds readily to the touch. Other types include hypertrophic, necrotic and sclerotic variants. The genitals are affected in 90% of patients and the inguinal region in 10%. Extragenital lesions may involve the lip, gums, cheek, palate, pharynx, larynx and chest. The diagnosis is usually confirmed by microscopic identification of Donovan bodies in tissue smears. Donovan bodies can be seen in large, mononuclear cells as Gram-negative, intracytoplasmic cysts filled with deeply staining bodies that may have a safety-pin appearance. Histological changes include chronic inflammation with infiltration of plasma cells and neutrophils. A genital ulcer multiplex PCR that includes *C. granulomatis* has been developed. Azithromycin is the drug of choice. Improved STI control focusing on genital ulcers in the wake of the HIV epidemic has resulted in a significant decrease in the global burden of donovanosis.

# Bacterial Vaginosis

Phillip Hay • Verapol Chandeying

44

## Definition

Bacterial vaginosis (BV) is the most common form of vaginal infection in women of reproductive age. It is characterized by a replacement of the normal lactobacillus flora with an overgrowth of anaerobic/facultative bacteria, associated with a rise in pH above 4.5. It was formerly known as non-specific vaginitis, Haemophilus, Corynebacterium, or Gardnerella vaginitis, non-specific vaginosis, or anaerobic vaginosis; BV has not been linked to infections outside the vagina.

## History (Taxonomic Controversy)

Before 1955, leukorrhea and “non-specific vaginitis” were the terms most frequently used to describe BV. It was thought that mixed bacterial infections accounted for many otherwise unexplained vaginal discharges, even though the putative etiological agents could not be differentiated from bacterial organisms commonly inhabiting the vagina. Such cases were often classified as non-specific vaginitis, or vaginitis unrelated to *Trichomonas vaginalis* or *Candida albicans*,<sup>1</sup> despite the fact that no clearly defined clinical pattern for such disease has ever been delineated.

The concept of non-specific vaginitis was discredited by Gardner and Dukes in 1955. They provided the first clear evidence that *H. vaginalis* is associated with the vast majority of these cases.<sup>2</sup> The name *H. vaginalis* was widely accepted until 1961 when LaPage demonstrated that it had neither X nor V factors, which were characteristics of *Haemophilus species*. He suggested that *H. vaginalis* might belong to the genus *Corynebacterium*.<sup>3</sup> In 1963, Zinnemann et al. concluded that *H. vaginalis* was a gram-positive *Corynebacterium*, and proposed the name *Corynebacterium vaginale*,<sup>4</sup> which was endorsed by Dunkelberg et al. in 1969.<sup>5</sup> In the 1970s the proposed name was used despite the accumulating evidence that the organism was not a *Corynebacterium*<sup>6,7</sup> and Park and associates were of the opinion that there was no precisely appropriate genus designation for this organism.<sup>8</sup> In 1980, Greenwood et al. suggested the name *Gardnerella vaginalis* to establish a new genus; this was supported by Piot and colleagues.<sup>9,10</sup> Some clinicians use the

term *Gardnerella vaginalis* vaginitis or BV, whereas others use the term “anaerobic vaginosis.”<sup>11</sup> BV is associated with vaginal overgrowth not only of anaerobic bacteria, but also of certain species of facultative bacteria and genital mycoplasmas.<sup>12,13</sup> The term “vaginal bacteriosis” was proposed by Huth to emphasize an increase in vaginal bacteria.<sup>14</sup> Garrison encouraged the use of the term “bacterial vaginopathy,” retaining the abbreviation “BV.” The reason is that the suffix “osis” is applied to Greek stems only and should not be used with the Latin stem “vagin.”<sup>15</sup> However, the term bacterial vaginosis is still most commonly used to identify this syndrome.

## Epidemiology

BV is the most common abnormal vaginal condition and is the leading cause of abnormal vaginal discharge (AVD) accounting for up to 48% of the cases.<sup>16–18</sup> The reported prevalence of BV is dependent on varying diagnostic criteria. Gram stained scoring systems generally report higher rates of BV than those using Amsel criteria.

In various populations across the world 9–50.9% of sexually active asymptomatic women,<sup>19–24</sup> and 4.9–52% of pregnant women have laboratory indicators of BV.<sup>25–29</sup> Generally, higher rates are found in developing countries than industrialized ones, with black women appearing to have double the rates of white. Among adolescents, rates of 13–31.9% have been reported.<sup>30,31</sup> In four studies there was no significant difference in the prevalence of BV or *G. vaginalis* between the sexually active and virginal groups supporting the conclusion that BV is not an exclusively sexually transmitted disease.<sup>31–34</sup> A recent study from Australia has challenged this finding: associating BV with non-penetrative genital contact and finding none in those denying all forms of genital contact.<sup>35</sup> BV was found in 17.5–29.3% of women having termination of pregnancy,<sup>36–39</sup> and the use of antibiotic prophylaxis with metronidazole decreases the risk of upper genital tract infection and infective morbidity after first trimester termination of pregnancy by about 50%.<sup>36,39</sup> BV is more prevalent in women with tubal infertility (31.5%) compared to those with

non-tubal infertility (19.7%).<sup>40</sup> About 29% of lesbian women attending a specialist clinic had BV as did 72.7% of their partners, again supporting a contribution from sexual transmission.<sup>41</sup>

## Pathogenesis

Lactobacillus species dominate normal vaginal flora, accounting for up to 96% of bacteria present. Most women with Lactobacillus dominant flora have H<sub>2</sub>O<sub>2</sub>-producing lactobacilli. *L. crispatus* and *L. jensenii* appear to be more protective against BV emerging than *L. gasseri*.<sup>42</sup> In contrast to normal women, one-third of the women with BV have no lactobacilli, and the remainder have lower concentrations of non-H<sub>2</sub>O<sub>2</sub>-producing lactobacilli. Lactobacilli are present at concentrations of 10<sup>5</sup> to 10<sup>8</sup> colony-forming units (CFU)/ml of vaginal secretions in normal women, and H<sub>2</sub>O<sub>2</sub> produced by certain strains of lactobacilli is inhibitory for certain bacteria in the vagina, particularly catalase-negative bacteria that do not have the enzyme that detoxifies H<sub>2</sub>O<sub>2</sub>.<sup>43,44</sup> H<sub>2</sub>O<sub>2</sub> may inhibit the growth of bacteria either directly via the toxic activity of H<sub>2</sub>O<sub>2</sub> or by reacting with a halide ion in the presence of cervical peroxidase as part of H<sub>2</sub>O<sub>2</sub>-halide-peroxidase antibacterial system.<sup>45</sup> These inhibit not only bacteria, but also HIV and other viruses *in vitro*.<sup>46</sup> Additional factors secreted by lactobacilli include peptides such as defensins and bacteriocins.

## Microbiology Studies Using Culture or DNA Probes

Hillier and associates described the frequency and concentration of microorganisms by isolation from the vagina of pregnant women,<sup>43</sup> stratified by the Gram stain criteria.<sup>47</sup> Based on the mean log concentration, Lactobacillus was present at concentrations 10 times greater (at log 10<sup>7</sup> levels) than that of the next most abundant microorganism, *G. vaginalis* (at log 10<sup>6</sup> levels). The number of lactobacilli is significantly decreased in BV; the concentration is about 10-fold less. The concentration of *G. vaginalis* is found at mean log of 10<sup>7.7</sup>, *Mycoplasma hominis* 10<sup>5.2</sup>, anaerobic gram-negative rods 10<sup>6</sup>, and *Prevotella bivia disiens* 10<sup>5</sup>.

In BV, lactobacilli comprise 1% or less of the bacteria present in the vagina.<sup>43</sup> Giorgi and colleagues identified *L. crispatus* and *L. jensenii*, not *L. acidophilus* and *L. fermentum*, as the predominant vaginal Lactobacillus species that colonize asymptomatic women.<sup>48</sup> This was later confirmed by Antonio and colleagues.<sup>49</sup> Using a whole-chromosomal DNA probe, most of the subjects were found to be colonized by *L. crispatus* (32%), followed by *L. jensenii* (23%), a previously undescribed species designated L. 1086V (15%), *L. gasseri* (5%), *L. fermentum* (0.3%), *L. oris* (0.3%), *L. reuteri* (0.3%), and *L. vaginalis* (0.3%). H<sub>2</sub>O<sub>2</sub> was produced by 95% of *L. crispatus* and 94% of *L. jensenii* isolates.<sup>50</sup>

## Studies Using Newer Molecular Techniques

Molecular techniques have so far required considerable resources, so many studies have sampled small numbers of subjects. Several investigators have used 16S RNA amplification and fluorescence

*in situ* hybridization (FISH) to identify hitherto unidentified bacteria in vaginal samples from women with BV. The use of different 16S RNA primers in different laboratories produces variation<sup>51</sup> and the sequences do not completely match the target organism for all bacteria leading to underquantification of some. Despite this, the results from different labs show that some asymptomatic women have a flora consisting of solely or predominantly lactobacilli, others a mixed flora with many BV associated organisms and some less expected patterns such as solely Streptococci or predominantly Pseudomonas. These studies did not specify the stage of the menstrual cycle which could impact significantly on the flora identified.

Verstraelen and colleagues studied the flora of 100 pregnant and non-pregnant women with similar methodology.<sup>52</sup> Thirteen had BV or intermediate flora. They identified several novel bacteria from women with BV and stressed the association with *Atopobium vaginae*. Fredricks and colleagues studied eight women with normal flora and nine with BV.<sup>53</sup> They identified novel bacteria in women with BV: BVAB1-3 which are classified as Clostridiales. Other novel organisms included *Atopobium vaginae*, *Leptotrichia amnionii*, *Sneathia species*, *Megasphaera species*, and Eggerthella-like bacteria. They were also able to follow subjects longitudinally and demonstrate changes in the organisms present in women who developed BV or who were treated successfully. The other organism of interest is *Lactobacillus iners*. This is a low H<sub>2</sub>O<sub>2</sub> producing organism, found in 99% of women with BV and 92% of women with normal flora. It stains as a small gram-negative bacillus. In a subsequent study Fredricks and colleagues concluded that detection of appropriate organisms by PCR could be used for diagnosis of BV with sensitivities and specificities of 94–99%.<sup>54</sup>

The description of the biofilm that develops in BV by Swidsinski and colleagues<sup>55</sup> places *Gardnerella vaginalis* once again at the center of pathogenesis of BV. Using a broad range of fluorescent bacterial group-specific rRNA-targeted oligonucleotide probes they identified a biofilm, adherent to epithelial cells in vaginal biopsies from women with BV. In some women the biofilm covered the entire biopsy, in others it was more patchy. *Gardnerella* accounted for 90% of bacteria seen in the biofilm, with *Atopobium vaginae* the only other numerically important organism. Lactobacilli predominated in women with normal flora, but did not form a biofilm. They proceeded to look at biopsies from a small number of women following treatment with standard courses of oral metronidazole.<sup>56</sup> Three different subjects were biopsied each week following treatment allowing a cumulative follow-up of 5 weeks. The biofilm persisted even at one week after treatment, although the bacteria were metabolically less active shown by low amenability. The amenability appeared to increase with time, although only one subject relapsed to intermediate flora at the time of biopsy. The hypothesis that persistence of the biofilm after treatment is associated with relapse appears highly plausible.

The primary etiology of BV is uncertain. Some authors regard it as an imbalance of endogenous flora, whilst others hold that there is a sexually transmitted pathogen as a necessary cause.

## Risk Factors

These are summarized in Table 44.1. BV has many behavioral associations characteristic of an STI such as change of sex partner, condoms providing protection and an association with STIs.<sup>57–60</sup> However it can be regarded as “sexually enhanced,”<sup>61</sup> rather than exclusively sexually transmitted. The best evidence against sexual transmission is its occurrence in virgin women at a similar prevalence to non-virgin women in three cross sectional studies.<sup>31,34,62</sup> An Australian study however reported the absence of BV in women with no genital contact at all, suggesting that “true virgins” may not have BV.<sup>63</sup>

Gardner and Dukes, in an attempt to fulfill Koch’s postulates for *Gardnerella*, induced BV in very few women inoculated with a culture of organism, but in a high proportion of those receiving vaginal discharge from women with BV.<sup>64</sup> The high concordance of lesbian couples for BV status again suggests transmission of BV from one to the other.<sup>41,65</sup> Thus, in monogamous lesbian couples, BV was reported in 72.7% of women whose partners had BV, compared to 10% of those whose partner did not have BV.<sup>74</sup>

Vaginal pH may be critical in the development of BV. *In vitro* anaerobes do not grow in the presence of *Lactobacilli* at pH 4.0 but escape at pH 6.0.<sup>45</sup> Estrogen levels alter over the course of a menstrual cycle, being highest in the luteal phase when BV is less common.<sup>66</sup> The numbers of *Lactobacilli*, and proportion of women colonized by BV-associated organisms changes with mid-cycle. Semen has an alkaline pH, between 7 and 8, and it is estimated that vaginal *Lactobacilli* produce enough acid to reduce pH by 0.56–0.75 units/hour.<sup>67</sup> Therefore, frequent unprotected sex may trigger BV through raising the pH. Factors that disturb vaginal physiology such as vaginal douching<sup>68,69</sup> pessary use,<sup>70</sup> and malodorous gynecological cancer<sup>71</sup> appear to increase the risk of BV. Recent antibiotic intake,<sup>46,72</sup> oral contraceptive pills,<sup>68,73–75</sup> and condom use<sup>74</sup> have not been related to BV.

BV is associated with HIV in cross sectional studies<sup>76,77</sup> and in a prospective study of pregnant women in Malawi, in which women with BV were more likely to seroconvert during pregnancy (OR 3.7) and postnatally (OR 2.3).<sup>78</sup> However, BV is associated with genital

herpes,<sup>79</sup> itself a strong risk factor for HIV acquisition. Studies that do not control for herpes should therefore be regarded as preliminary.<sup>80</sup> Only one small study has examined the relationship between BV and non-gonococcal urethritis (NGU) in male partners.<sup>81</sup> There were 39 men with NGU. Female partners of 12 (31%) had BV, compared to only 1 (8%) of the female contacts of the 12 men without NGU. In most studies BV is more common in women diagnosed with STIs including herpes, Chlamydia, gonorrhea and pelvic inflammatory disease.<sup>82</sup> This is discussed further under complications. One further argument against BV being sexually transmitted is the failure of partner treatment to reduce the relapse rate of BV in treated women. Several studies show that the treatment, with metronidazole or clindamycin, of male partners of women with BV has little effect on the recurrence of BV.<sup>83–86</sup> If there is a sexually transmitted agent, it is therefore not readily eliminated in men by these antibiotics.

## Biochemical Changes

The bacteria associated with BV produce a number of virulence factors. These include lipopolysaccharidases, sialidases, and mucinases.<sup>87,88</sup> Some strains of *G. vaginalis* cause cleavage of secretory IgA.<sup>89</sup> Anaerobic bacteria produce aminopeptidases that degrade protein and decarboxylases that convert amino acids and other compounds to amines such as putrescine, cadaverine, and trimethylamine. These amines contribute to raising the vaginal pH and produce the characteristic smell of BV.<sup>90,91</sup> The ratio of succinate, produced by anaerobic metabolism, to lactate, produced by *Lactobacilli* is increased.<sup>92</sup> These microbial substances and virulence factors collectively play a role in overcoming cervical host defense barriers leading to the ascent of microbes into the upper reproductive tract. They collectively cleave mucus leading to the thin homogenous discharge that is characteristic of BV. Transport of BV microflora and their products contributes to deciduitis and fetal membrane infection during pregnancy.<sup>88</sup>

The enzymes produced by bacteria found in BV can cleave IgA<sup>89</sup> and other protective factors such as secretory leukocyte protease inhibitor (SLPI). SLPI is found in saliva and vaginal fluid and inhibits HIV entry into cells. Levels were significantly reduced in vaginal fluid from women with BV.<sup>93</sup> Although BV has not been studied as risk factor for female to male transmission of HIV, women with HIV shed more virus into the cervico-vaginal discharge when BV is present.<sup>94</sup>

## Clinical Manifestations

In clinical practice the typical symptoms of BV are an unpleasant fishy smell and thin discharge.<sup>95,96</sup> In some women one or other manifestation predominates. Gardner commented that “practically all patients with BV were conscious of a disagreeable odour.”<sup>92</sup> The smell is more obvious after unprotected intercourse or with menstruation when elevated pH makes the amines more volatile.<sup>97</sup> About half the women with BV do not report any symptoms.<sup>98,99</sup> There is usually no inflammation. Occasionally women develop soreness of the vulva from maceration due to continual wetness.

**Table 44.1:** Risk Factors for Bacterial Vaginosis

Factors positively associated with BV	Factors negatively associated with BV
Black ethnicity	Oral contraceptive use
Intrauterine contraceptive device*	Condom use
Smoking	
Vaginal douching	
New male or female sex partner	
Receptive cunnilingus or anal sex	
Sexually transmitted infections, e.g., Chlamydia, HSV-2	

\*A recent review of the relationship between BV and intrauterine contraceptive device concluded that there is no convincing evidence of an association.<sup>204</sup> Studies that reported one did not adjust for confounding factors adequately.

On examination the discharge is described as milky or homogeneous, low in viscosity, white or grayish, and free of grossly visible crumbs of epithelial cells that are seen in normal vaginal secretion (flocular). Sometimes it is frothy, although this is usually seen with trichomoniasis. The fishy smell may be readily detected during examination in some women.

Whilst the clinical presentation of BV is easily recognized it is surprising that in a study of 2888 women attending for routine healthcare in Birmingham, Alabama women with BV did not report vaginal symptoms any more than women without BV.<sup>100</sup> Women with gonorrhea, Chlamydia, or trichomonas were excluded. In the past 6 months 75% of women with and 82% of women without BV never noted any vaginal odor. The corresponding values were 63% and 65% for never noting vaginal “wetness”; 58% and 57% for vaginal discharge; 91% and 86% for irritation; 88% and 85% for itching; and 96% and 94% for dysuria, respectively. Cumulatively, 58% of women with BV noted odor, discharge, and/or wetness in the past 6 months compared with 57% of women without BV.

In a gynecology clinic, around 49% of women with BV complained of malodor, compared with 20% without BV.<sup>98</sup> The reasons for this are complex but include embarrassment, believing it is a reflection of their personal hygiene, or normal. On the other hand some women experience stigma and discrimination because they perceive that others are detecting the smell. Thus, although BV is usually a benign condition, its symptoms make it an important cause of mental distress.

## Diagnosis

The presenting symptoms alone are not reliable for the diagnosis of BV. It can co-exist with the other common causes of abnormal discharge: candidiasis, trichomoniasis, and cervicitis, leading to atypical symptoms and signs. Even when BV is the only abnormality present it can be atypical.

The Amsel criteria are used for clinical diagnosis in many settings.<sup>101</sup> At least three of the following four signs must be present:

- Vaginal pH > 4.5,
- Homogeneous discharge,
- Positive amine test,
- Clue cell constituting 20% or more of total vaginal epithelial cells.

Clue cells, first described by Gardner as giving “a clue to the diagnosis,”<sup>92</sup> are epithelial cells coated with a thick film of small bacteria such that the border of the cell is obscured. The amine test is positive if addition of alkali, traditionally 10% KOH releases a strong fishy smell. These simple clinical tests are inexpensive and available in most office settings, requiring narrow range pH paper, 10% KOH, and saline, a microscope slide and microscope. Their limitations have been discussed many times. They all require subjective interpretation, and cannot be verified subsequently without re-examining the patient. The presence of clue cells is the most specific sign, but the specificity was increased by using a cut-off of at least 20% epithelial cells being clue cells.<sup>98</sup> Typical

discharge may not be apparent even to the experienced observers: in one study this was the least reliable sign.<sup>102</sup> The amine test has low sensitivity,<sup>98</sup> and may be falsely positive if semen is present. The liquefaction of the semen may yield a homogeneous secretion, and raise the pH level as well.<sup>95</sup> If cervical mucus is inadvertently sampled it yields a pH as high as 7.0. Recent use of vaginal douches or medications may also cause diagnostic difficulty. Smears from women with trichomoniasis are usually deficient in Lactobacilli and have a high number of polymorphonuclear cells, but may not have typical clue cells to allow a definitive diagnosis of co-existent BV. Since the antibiotic treatment is the same the distinction is irrelevant for clinical practice.

One further limitation with the Amsel criteria is that they define a cut-off between normal and BV. It is now clear that there is a continuum between normal and BV in terms of the concentrations of bacteria present and the diversity of the vaginal flora. This makes it almost impossible for there to be 100% agreement between different diagnostic modalities. The systems for interpreting Gram-stained vaginal smears that were developed subsequently recognize intermediate grades of flora which increases precision in research studies. Nevertheless, the Amsel criteria are generally very good at identifying symptomatic patients in clinical practice.

BV is readily recognizable on Gram stain of vaginal fluid (Fig. 44.1). Slides can be stored for months and verified independently, which allows quality control in multi-centre studies. Intermediate grades of flora can be recognized. The reagents used are inexpensive and readily available. Absent or reduced lactobacilli are replaced by high concentration of Gardnerella morphotypes sometimes accompanied by curved rods (*Mobiluncus* morphotypes). Nugent and colleagues provided a method to standardize the Gram stain interpretation of BV.<sup>47</sup> A score between 0 and 10 is derived from a weighted combination of the following: (i) large gram-positive rods (lactobacilli), (ii) small gram-negative or variable rods (*Prevotella* spp. or *G. vaginalis*), and (iii) curved gram-negative or variable rods (*Mobiluncus* spp.). Each group is quantitatively weighted on a scale of 0 to 4:

- 0 = no morphotype per oil field;
- 1+ = less than one morphotype per oil field;
- 2+ = one to four morphotypes per oil field;
- 3+ = five to 30 morphotypes per oil field;
- 4+ = more than 30 morphotypes per oil field.

Plentiful Lactobacillus morphotypes are considered normal: therefore the score is inversely related to the number of organisms: 4+ lactobacillus scores 0, 3+ scores 1 and so on. For Gardnerella morphotypes the score correlates to the number of organisms: 4+ Gardnerella gives a score of 4 and so on. Mobiluncus is similarly correlated but weighted lower, so 1+ and 2+ organisms scores 1 and 3+ and 4+ score 2. Therefore a Gram stain with “severe BV” scores 10: 4 for absence of Lactobacillus morphotypes; 4 for 4+ Gardnerella morphotypes; and 2 for 4+ Mobiluncus morphotypes. A “normal” Gram stain scores 0: 0 for 4+ Lactobacillus morphotypes, 0 for 0 Gardnerella morphotypes, and 0 for 0 Mobiluncus morphotypes.

\*c+

\*d+

**Fig. 44.1:** (a) Gram-stained vaginal smear from woman with BV, Nugent score 10. In the high power field there are no *Lactobacillus* morphotypes, greater than 30 *Gardnerella* morphotypes (curved rods), and between 5 and 30 *Mobiluncus* morphotypes (curved rods). The edge of an epithelial cell is shown on the right. It is covered with bacteria resembling a clue cell. (b) Gram-stained vaginal smear from a woman with normal flora, Nugent score 0. The flora is dominated by *Lactobacillus* morphotypes (Gram-positive rods, >30/high power field). The edges of the epithelial cells are seen clearly, with few bacteria. There is a polymorphonuclear cell at the top right corner.

A total score of 7 to 10 (the sum of rating score of those three groups) is considered to be indicative of BV, a score of 4 to 6 intermediate flora, and 0 to 4 normal flora. The sensitivity and specificity of Nugent's criteria, compared with Amsel's criteria were 83.3% and 92.1%, respectively<sup>103</sup> but Nugent scoring requires a skilled operator and can be time consuming.

In the UK a simpler method is recommended for use in Genitourinary Medicine clinics. The Hay–Ison criteria relies

more on pattern recognition, assessing the relative proportions of bacterial morphotypes.<sup>104,105</sup>

- Grade I (normal flora), *Lactobacillus* morphotype only or pre-dominant
- Grade II (intermediate flora), reduced *Lactobacillus* morphotype with mixed bacterial morphotypes;
- Grade III (BV), mixed bacterial morphotypes with few or absent *Lactobacillus* morphotypes.

Two additional grades are used also;

- Grade 0, epithelial cells with no bacteria seen
- Grade IV, epithelial cells covered with Gram positive cocci only

In an international workshop the inter-observer variability using the Nugent and Hay scoring systems was equally good for both.<sup>106</sup>

Detection of biochemical changes in vaginal fluid is an alternative way of making the diagnosis but not often used routinely. Gas-liquid chromatography had 78% sensitivity and 81% specificity in pregnant women.<sup>107</sup> Several criteria for abnormality were used: a succinate:lactate ratio greater than or equal to 0.4 or elevated peaks of acetate, propionate, isobutyrate, or isovalerate. The commercially available point-of-care test BVBlue measures sialidase, and performs well.<sup>108</sup> A recent evaluation reported sensitivity of 88% compared to both Nugent and Amsel criteria with specificity of 95% and 91%, respectively.<sup>109</sup>

Traditional qualitative culture is not reliable for diagnosis. Up to 60% of women without BV are colonized with *G. vaginalis*.<sup>17,107</sup> Therefore, isolation of *G. vaginalis* for diagnosis of BV without additional indicators is not helpful. High concentrations do correlate better with BV,<sup>110</sup> but quantitative aerobic and anaerobic vaginal cultures are costly and impractical for clinical use.<sup>111,112</sup> The Affirm VPIII uses DNA hybridization to detect high levels of *Gardnerella*. A recent evaluation reported a sensitivity of 87.7% and a specificity of 96.0% compared to Nugent scoring.<sup>113</sup>

Another test is the FemExam (Litmus Concepts Inc., Santa Clara, CA). FemExam card 1 has indicators for pH greater than or equal to 4.7 and one for amines greater than 0.5 mmol, card 2 measures proline iminopeptidase activity. A recent evaluation against Nugent criteria reported that FemExam card 1 had a sensitivity of 71.4% and specificity of 72.8%, FemExam card 2 a sensitivity of 70% and specificity of 81.0%.<sup>114</sup> and FemExam cards 1 and 2 combined had a sensitivity of 91.0% and specificity of 61.5%. Such tests may have some utility where there is no access to a microscope but incur greater reagent costs.

It is likely that identifying some of the newly identified bacteria found in BV using molecular techniques will provide highly specific and sensitive diagnosis of BV. When such tests become available they may replace Gram stain reading in research studies and eventually for clinical diagnosis if they become affordable. Detection of either *Megasphaera* or one of the *Clostridiales* bacteria (BVAB1-3) gave a sensitivity of 99% and specificity of 89% compared to Amsel criteria and a sensitivity of 95.9% and a specificity of 93.7% compared to Nugent criteria.<sup>54</sup> Fredricks and colleagues concluded

that “PCR detection of one or more fastidious bacterial species is a more reliable indicator of BV than detection of bacteria, such as *Gardnerella vaginalis*, previously linked to BV, highlighting the potential of PCR for the diagnosis of BV.”

## Complications

The symptoms of BV can be distressing for those with frequent recurrences. It can adversely affect sexual and family relationships and working lives, and lead to depression. BV is associated with an increased risk of many adverse outcomes summarized in Table 44.2.

In cross-sectional<sup>76,77,115</sup> and prospective studies<sup>78</sup> BV was a risk factor for acquisition of HIV (discussed in risk factors). In a prospective study of 657 Kenyan commercial sex workers absence of lactobacilli was predictive of acquiring HIV-1 infection (HR, 2.0; 95% CI 1.2–3.5) and gonorrhea (HR, 1.7; 95% CI, 1.1–2.6).<sup>50</sup> Presence of abnormal vaginal flora on Gram's stain was associated with increased risk of both HIV-1 acquisition (HR, 1.9; 95% CI, 1.1–3.1) and Trichomonas infection (HR, 1.8; 95% CI, 1.3–2.4). An interesting study of 255 women presenting as contacts of male partners with Chlamydia or gonorrhea found that those with BV were more likely to harbor *Neisseria gonorrhoeae* (OR 4.1; 95% CI, 1.7–9.7) and/or *Chlamydia trachomatis* (OR 3.4; 95% CI, 1.5–7.8).<sup>116</sup> This does not mean that BV necessarily increases susceptibility to STIs as it is possible that the STIs alter the vaginal environment, maybe through increased production of purulent cervical discharge of high pH, triggering BV. However, a prospective study that used serology to identify women with HSV-2 infection found that those with BV at baseline had a twofold greater risk of seroconversion over the course of a year.<sup>79</sup> In an intriguing study 107 women attending an STD clinic with asymptomatic BV were randomized to receive a 5-day course of metronidazole gel followed by twice weekly use for six months, or no treatment.<sup>117</sup> Either due to a lack of efficacy of the regimen or poor adherence BV recurred in more than 50% women in the metronidazole group, and regressed in about 30%

of those allocated to no treatment. Nevertheless, there was a significant reduction in the rate of Chlamydia infection over 12 months (3/53, 8.6% vs. 13/54, 27.1%), although not for other STIs. The accompanying editorial recognized the difficulties of performing this type of study, and its limitations and concluded that there is not sufficient evidence to recommend such an approach routinely.<sup>118</sup> Urinary tract infection in women is linked to persistence of *E. coli* in the vagina. Since lactobacilli inhibit *E. coli*, it is not surprising that BV was associated with a nearly threefold increased rate of UTI in a cross-sectional study.<sup>119</sup>

Many bacteria recovered from the tubes and pelvic abscesses of women with PID are those associated with BV.<sup>120,121</sup> In cross sectional studies BV is more prevalent in women with PID than those without.<sup>93</sup> Plasma cell endometritis, which is a histological correlate of PID, was associated with BV, albeit only just reaching statistical significance (15, 95% CI 2–686).<sup>122</sup> The GIFT study prospectively evaluated 1179 women over up to four years.<sup>123</sup> BV was associated with endometritis in a subset of 278 women (OR, 2.4; 95% CI, 1.3–4.3).<sup>124</sup> BV alone was not a risk factor for PID, but amplified the risk of PID three-fold if there was concurrent Chlamydia or gonorrhea (OR 3.1; 95% CI, 1.64–5.87).

BV is linked to infections after pelvic surgery. Thus women with BV had higher rates (RR 3.2; 95% CI, 1.5–6.7) of cuff cellulitis after abdominal hysterectomy.<sup>125</sup> In a Swedish study cuff cellulitis or wound infection occurred in 35% (7/20) of those with BV and 8% (4/50) (OR 6.2; 95% CI, 1.3–30.7) of those without BV.<sup>126</sup> BV is a risk factor for endometritis after surgical termination of pregnancy. Clue cells identified pre-operatively were associated with an 5.6-fold (95% CI, 1.8–17.2) increased risk of infection.<sup>127</sup> Several RCTs of treatment before termination have shown benefit: Larsson and colleagues reported a 3-fold reduction with 10 days oral metronidazole in a study of 174 women,<sup>128</sup> and a 4-fold reduction from use of clindamycin cream.<sup>129</sup> In the UK, Crowley and colleagues reported a 50% reduction with a single 2 g suppository of metronidazole, but this just failed to reach statistical significance.<sup>39</sup> A study from the USA did not demonstrate a significant benefit, but there was trend for benefit from oral metronidazole in the 154 women with BV (RR 1.6; 95% CI, 0.9–3.0).<sup>130</sup> Most women undergoing Caesarean section currently receive antibiotics including metronidazole. In a setting before this became the practice, BV was associated with a 6 fold increased risk of postpartum endometritis.<sup>131</sup> In a randomized study of women with or without BV, a single intravaginal dose of metronidazole reduced the risk of post-Caesarean endometritis by 60% (RR 0.42; 95% CI, 0.19–0.92).<sup>132</sup>

## PREGNANCY COMPLICATIONS

Complications following termination of pregnancy and Caesarean section have been discussed in the previous section. BV has been associated with complications throughout pregnancy. Endometritis, which is associated with BV, is likely to be unfavorable to implantation. Thus, in women undergoing IVF isolating H<sub>2</sub>O<sub>2</sub> producing lactobacilli or no bacteria from the tip

**Table 44.2:** Complications Associated with Bacterial Vaginosis

All women:
Acquisition of sexually transmitted infections, including HIV, Gonorrhea, Chlamydia, HSV
Urinary tract infection
Upper genital tract infection: spontaneous PID and post-abortion endometritis
Post hysterectomy cuff cellulitis and wound infection
Pregnancy:
Reduced chance of successful IVF
Second trimester miscarriage
Spontaneous pre-term birth, pre-term pre-mature rupture of membranes, low birth weight
Post Cesarean section endometritis

of the catheter used for implantation of an embryo is associated with a higher rate of successful pregnancy, and isolating bacteria associated with BV with poorer outcome.<sup>133</sup> In a UK study BV was associated with a greater rate of early pregnancy loss in women undergoing IVF (OR 2.67; 95% CI, 1.26–5.63).<sup>134</sup>

During pregnancy chorioamnionitis, which is strongly associated with pre-term birth, can develop from bacteria already present in the endometrium or those continuing to ascend from the vagina.<sup>135</sup> Further spread leads to deciduitis, amniotic fluid infection, fetal infection and ultimately fetal death from sepsis. The release of inflammatory mediators including IL-1, IL-6, and TNF- $\alpha$  stimulate production of prostaglandins, the final pathway for initiating labor. The cytokines, endotoxins, and exotoxins also initiate neutrophil chemotaxis, infiltration, and activation, leading to release of metalloproteases which denature the membranes, leading to rupture and they also soften the cervix.<sup>136</sup>

Many studies have investigated the relationship between BV and adverse pregnancy outcomes. Initial case control studies demonstrated an association before prospective cohort studies confirmed it. BV is associated strongly with second trimester miscarriage, with odds ratio up to 5.<sup>105,111</sup> BV is associated with intra-amniotic fluid infection,<sup>137,138</sup> chorioamnionitis leading to pre-term delivery,<sup>139</sup> pre-mature rupture of membranes (OR 7.3).<sup>140</sup> A meta-analysis in 2003 concluded that BV doubles the risk of pre-term birth (OR 2.19; 95% CI, 1.54–3.12).<sup>141</sup> The largest single study from the USA involving 12,937 women reported a smaller effect (OR 1.2; 95% CI, 1.1–1.4).<sup>142</sup> Two recent studies using modified criteria for diagnosis reported that lack of lactobacilli, and/or markers of inflammation were stronger predictors of adverse outcome than BV. Donders and colleagues include aerobic vaginitis, in which there are reduced lactobacilli with parabasal cells, cocci and coliforms, and neutrophils.<sup>143</sup> They found that such disturbed flora, and absence of lactobacilli were more predictive of pre-term birth than standard BV.<sup>144</sup> Verstraelen and colleagues identified a variant of normal flora<sup>145</sup> accompanied by atypical gram-positive bacteria and neutrophils which was more strongly associated with pre-term birth than BV,<sup>146</sup> with an odds ratio of 5.2 (95% CI, 1.8–14.5).

The microorganisms found in BV are also commonly found in the amniotic fluid of women with amniotic fluid infection.<sup>147</sup> Bacteria associated with BV make up about one half of the isolates from amniotic fluid of women in pre-term labor with intact membranes.<sup>148</sup> Using a combination of culture and PCR DiGiulio and colleagues identified bacteria in 15% of 166 women presenting in pre-term labor with intact membranes.<sup>149</sup> All these women delivered pre-term and had greater rates of chorioamnionitis (OR 20; 95% CI, 2.4–172). In a subsequent paper they showed that the presence of bacteria was associated with higher levels of polymorphs and IL-6.<sup>150</sup> The range of bacteria identified are shown in Fig. 44.2. They are predominantly BV-associated or Ureaplasma.

In summary there is good evidence that BV/abnormal vaginal flora is predictive of spontaneous pre-term birth and that the majority of bacteria found in chorioamnionitis and amniotic

fluid infection are BV-associated or Ureaplasma. Furthermore, the presence of bacteria is associated with an inflammatory response and pre-term birth. Identifying and treating BV early in pregnancy might therefore be expected to reduce adverse pregnancy outcome.

Several studies have investigated the use of oral metronidazole,<sup>151–153</sup> oral clindamycin,<sup>154,155</sup> and topical clindamycin<sup>88,156–159</sup> in the second or third trimester of pregnancy to treat BV as a way of preventing pre-term birth (PTB). One study used a combination of erythromycin and metronidazole.<sup>160</sup> Some studies showed a statistically significant reduction in late miscarriage,<sup>154</sup> and pre-term birth,<sup>151,154,155,159,160</sup> some no difference,<sup>88,152,153</sup> and some a trend for worse outcome with topical clindamycin treatment.<sup>156–158</sup> Systematic reviews have reached varying conclusions: including Cochrane which concluded “... little evidence that screening and treating all pregnant women with asymptomatic BV will prevent PTB and its consequences. However, there is some suggestion that treatment before 20 weeks’ gestation may reduce the risk of PTB.”<sup>161</sup> U.S. Preventive Services Task Force found that “No benefit was found in treating women with low- or average-risk pregnancies for asymptomatic bacterial vaginosis.”<sup>162</sup> A Canadian review concluded that “Macrolides and clindamycin, given during the second trimester of pregnancy, are associated with a lower rate of pre-term delivery, whereas second-trimester metronidazole used alone is linked with a greater risk of pre-term delivery in a high-risk population.”<sup>163</sup> Neither US CDC guidelines, nor UK recommend routine screening and treatment for BV, but allow the clinician to decide in high risk pregnancies.

One further study should be mentioned. Kiss and colleagues in Vienna screened 4429 women for BV, candida and Trichomonas in the second trimester of pregnancy.<sup>164</sup> Those randomized to intervention were treated with topical clotrimazole, clindamycin and metronidazole respectively. There was a reduction in pre-term birth for the intervention group: 3.0% vs. 5.3% (95% CI 1.2–3.6). Surprisingly most of the difference was in women treated for candida rather than BV, and very few had Trichomonas. This study needs replicating, but supports the concept of treating vaginal infections to prevent pre-term birth.

## Treatment

Treatment is indicated for symptomatic BV. If “asymptomatic” BV is found many clinicians discuss the specific symptoms in detail as they may have been concealed initially due to embarrassment. Genuinely asymptomatic BV does not need treatment. Even though BV is associated with many adverse sequelae there is no evidence that treating it makes a substantial difference to whether it will be there subsequently, except possibly in pregnant women in whom BV appears to occur at a low rate.<sup>165</sup> In the Rakai study of mass treatment for STIs to prevent HIV infection there was no reduction in the prevalence of BV following mass treatment of men and women with metronidazole and other antibiotics except in women who were pregnant.<sup>24,166</sup> The GYN Infections follow-through Study (GIFT) recruited predominantly young

**Fig. 44.2:** Microbial diversity of bacteria found in amniotic fluid of women in pre-term labor. Microbial diversity: Phylogeny of the 17 bacterial taxa identified in this study, based on a maximum likelihood algorithm. Colored boxes indicate the number of subjects who were positive for a given taxon by culture (gray) or PCR (blue) (some samples were polymicrobial). For most individual taxa, the larger of the two numbers in the corresponding gray or blue box represents the total number of positive subjects; for taxa where neither method detected all positive subjects, the total number is shown in the white box. A 99% sequence similarity cutoff threshold was used for phylotype assignment, which was based on 621 unambiguous nucleotide positions. *Bergeyella* sp. (bracketed and in gray type) is included as a reference species only and was not detected in the study population. A single fungal species, *Candida albicans*, was detected by culture in 1 subject and by PCR in 2 (data not shown). Reproduced from reference 149.

black women considered to be at high risk for STI acquisition.<sup>167</sup> Ness and colleagues showed that the likelihood of changing Nugent score between visits (every 6 or 12 months) was normally distributed; that is, BV resolved in as many women as in whom it developed.

After Gardner and Dukes<sup>2</sup> identified what we now call *G. vaginalis*, therapy was directed towards the organism with oral tetracycline, a triple sulfa vaginal cream and subsequently ampicillin. Metronidazole and clindamycin were employed after the importance of anaerobic organisms was recognized in the late 1970s.<sup>168</sup> The clinical definition of BV makes evaluation of treatment difficult: it includes women without symptoms, who may not need treatment, and there has not been a standard definition of cure, for example, less than 3 Amsel criteria or none? Variations in the reported therapeutic efficacy often can be attributed to a number of methodological differences, such as different study populations, diagnostic criteria, length of follow-up, and definition

of cure. Duration of follow-up is probably the most important variable in determining the effectiveness. By current standards few comparative studies, other than those employing placebo have been adequately powered to show non-inferiority.

Most therapies recommended for BV in non-pregnant women are successful in the short term, but relapse over 1–3 months occurs in greater than 50% treated women. Metronidazole and clindamycin are the drugs studied most frequently and therefore recommended in guidelines. The current CDC guidelines favor metronidazole 400 mg twice daily for 7 days as the most reliable treatment, based on a detailed review of all published studies.<sup>169</sup> The estimated efficacy was 80–90%. Alternative treatments may be preferred by women with recurrent BV, or those for whom metronidazole is contra-indicated. These are oral metronidazole or tinidazole as a single 2 gram dose, topical metronidazole 0.75% gel applied daily for 5 days, or 2% clindamycin cream applied daily for 5 days.

Metronidazole was first introduced for the treatment of trichomoniasis. Its therapeutic use has subsequently been expanded to include protozoal and anaerobic infections, including BV. Metronidazole given orally is absorbed almost completely. Metronidazole has limited plasma protein binding and favorable tissue distribution. The drug is extensively metabolized by the liver to form 5-oxidative metabolites. Majority of the drug and its metabolites are excreted in the urine and feces. The half-life is 6 to 10 hours. Metronidazole is generally well-tolerated at less than 2 g per day, for short periods. The commonest toxicity is gastrointestinal, a metallic taste, anorexia and nausea which tends to increase over successive days. It has a disulfiram-like effect with alcohol leading to hangovers. Interactions with warfarin and phenytoin have been reported. Mutagenesis and carcinogenesis are only described in mice. Several meta-analyses have concluded that there is no evidence of teratogenicity in humans and it can be used in the first trimester of pregnancy.<sup>170–172</sup> Fortunately bacterial resistance, both clinical and microbiological, has been described only rarely.<sup>173</sup> Serum metronidazole concentrations after intravaginal administration of 0.75% gel were only 2% of the concentrations achieved with the standard 500 mg oral dose.<sup>174</sup> Not surprisingly systemic side effects are therefore uncommon.<sup>175,176</sup>

Clindamycin is also an effective treatment for BV, but is more expensive and is associated with diarrhea and, infrequently, pseudomembranous colitis.<sup>177</sup> It is also more active against lactobacilli, although this has not translated into reduced efficacy compared to metronidazole.<sup>178,179</sup> The oral dose of 300 mg twice daily has not been studied extensively outside of pregnancy, but appears to have efficacy similar to metronidazole.<sup>180</sup> The topical preparation of clindamycin contains mineral oils, which may weaken latex condom and diaphragms. There is less than 5% systemic bio-availability.<sup>181</sup> In non-pregnant women, topical clindamycin 2% vaginal cream or metronidazole vaginal gel have rates of cure similar to those for oral metronidazole.<sup>182–184</sup> However resistance in some bacteria such as *Prevotella* appears to be selected rapidly, leading to caution in long-term use of clindamycin.<sup>185</sup>

One complication common to all treatments is vaginal candidiasis. It has been reported in varying proportions: 8.5% after oral metronidazole,<sup>183</sup> 21% with metronidazole vaginal gel,<sup>186</sup> and 4.7% with clindamycin vaginal cream.<sup>183</sup>

Other agents, some with good anti-anaerobic activity, have been studied with cure rates reported as follows:

- Tinidazole, 2 g orally single dose—51%,
- Tinidazole, 2 g orally on 2 consecutive days—74%<sup>187</sup>; (Tinidazole was superior to placebo using stringent criteria for cure, using 1 gram daily for 5 days 36.8% were cured compared to 5.1% [ $p < 0.001$ ])<sup>188</sup>
- Secnidazole, 2 g orally single dose—59–96%<sup>189</sup>;
- Amoxicillin + clavulanic acid, 500 mg three times daily for 7 days—70%<sup>190</sup>; amoxicillin, 500 mg three times daily for 14 days—no significant difference compared with placebo<sup>191</sup>;

- Triple sulpha vaginal cream—41.8%<sup>192</sup>;
- Erythromycin, 500 mg orally twice daily for 7 days – 19%.<sup>193</sup>

## ALTERNATIVE TREATMENTS

Probiotics and prebiotics have been studied as a treatment for gastrointestinal conditions. Vaginal lactobacilli differ from those considered optimal for the gut, but several vaginal strains are now available. Another approach is to use lactic acid gel to acidify the vagina. Both approaches have been evaluated in small studies of variable quality so there is insufficient evidence to support their routine use in current guidelines.<sup>194–196</sup> They may however be useful adjunctive treatments.

## TREATMENT OF MALE PARTNER(S)

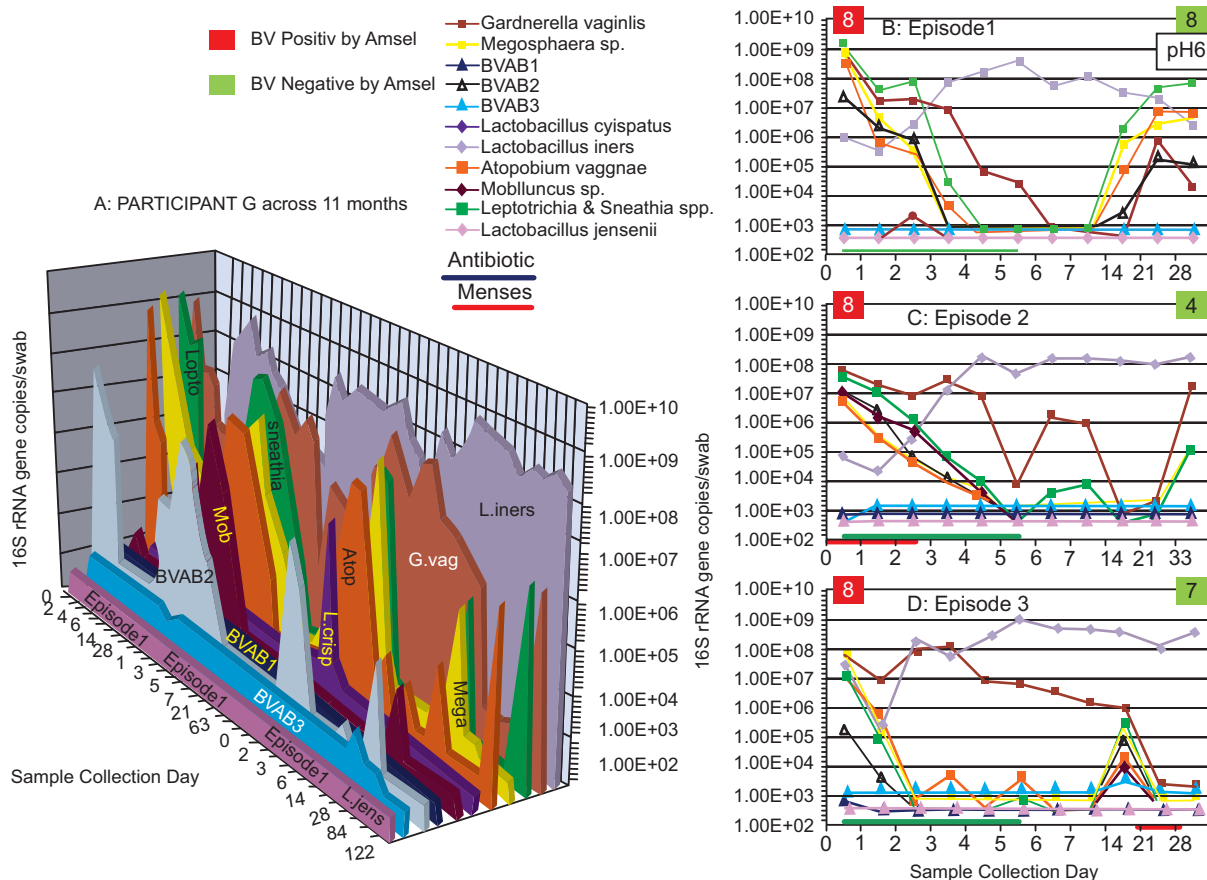

One of the arguments against BV being an STI is that treatment of male partners with antibiotics used for BV has not reduced the rate of recurrence in female partners.<sup>197</sup> Several randomized trials in which metronidazole therapy was given to male sexual partners of women with BV, failed to demonstrate any effect on the recurrence of BV.<sup>83–85</sup> One study used clindamycin for male partners and again found no difference in recurrence rates.<sup>86</sup> There is therefore no indication for treatment of male partners of women with BV. However, given the high rate of NGU reported in male partners of women with BV attending an STD clinic<sup>81</sup> it is reasonable to screen male partners of women with recurrent BV for STIs.

## Recurrent BV

The propensity of BV to recur remains frustrating for those affected by it, and in severely affected women, it can lead to depression and adversely affect relationships.<sup>195</sup> It is important at a public health level because we have not identified how to reduce many of the associated complications. Are the factors that trigger a first episode the same as those that trigger recurrence? The flora can be in a very dynamic state with rapid changes over the course of a menstrual cycle. This can be shown by collecting vaginal smears for Gram staining,<sup>198</sup> or more recently by quantitative 16S RNA detection,<sup>199</sup> shown in Fig. 44.3.

An Australian study followed a cohort of 121 women treated for BV with metronidazole for 7 days.<sup>200</sup> Over the course of a year 58% had a recurrence of BV, and 69% had a recurrence of abnormal vaginal flora (Nugent score 4–10) by 12 months. Recurrence was associated with a past history of BV; a regular sex partner throughout the study; and female sex partners.

How can we prevent relapse? Sobel and colleagues recruited 157 women with BV at presentation and a history of at least two episodes in the previous 12 months.<sup>201</sup> They randomized 112 women who had no symptoms of BV and fewer than three Amsel criteria positive after an initial 10-day course of metronidazole gel. They received metronidazole gel or placebo

**Fig. 44.3:** Temporal fluctuations in bacterial concentrations in a woman with recurrent BV. Bacterial fluctuations in a participant with recurrent BV: Figure A depicts dynamic patterns of BV bacteria in Participant G across a period spanning 11 months. She was diagnosed with BV by Amsel's and Nugent's criteria at entry (Episode 1, B), and was responsive initially to treatment. However, she had two more episodes subsequently (C and D) and each time she responded to metronidazole treatment but had a return of BV-associated bacteria and went on to develop BV. Reproduced from Srinivasan et al.<sup>199</sup>

twice weekly for 16 weeks with a further 12 weeks of follow-up off therapy. During suppressive therapy, there were recurrences in 13 women (25.5%) receiving metronidazole and 26 (59.1%) receiving placebo (RR 0.43; 95% CI, 0.25–0.73). By the end of week 28, however, recurrences occurred in an additional 13 women randomized to metronidazole gel and seven to placebo, which suggests little if any long-term benefit from suppression of this duration. Secondary vaginal candidiasis occurred significantly more often in metronidazole-treated women. An earlier single blind study showed that nystatin and metronidazole ovules produced a lower relapse rate than metronidazole gel alone.<sup>202</sup> It is the practice of the author to prescribe weekly antifungal treatment with metronidazole gel suppression for women with recurrent BV and a history of vaginal candidiasis.

Might more prolonged courses of treatment, or combinations of antibiotics be more effective? Schwabke tested the hypotheses that adding azithromycin to a metronidazole regimen would improve cure because of greater activity against some BV organisms such as *Mobiluncus curtisii* and *Mycoplasmas*, or

that prolonging the duration of metronidazole therapy from 7 to 14 days would be more effective.<sup>203</sup> It was adequately powered with 568 women randomized across the 4 arms. Seven days after treatment finished there was a significant benefit for the 14-day course of MTZ compared to 7 days with 44.8% cured compared to 63.4%. This benefit was lost at day 21 after treatment completion, and there was no benefit from adding azithromycin to the regimen. Certainly neither approach seems to be the answer. It may be that combinations of treating male partners, probiotics and lactic acid gel are required. Even with metronidazole gel suppression twice a day some breakthrough occurs. There is also the same dilemma as in managing recurrent herpes and candida: the trials of suppressive therapy give data for 6 months, but patients need long-term management, and may require very prolonged suppression. If recurrence does not occur every month it is often preferable to give a woman several treatment courses to initiate treatment when symptoms recur so that she does not have to take time off to arrange an urgent appointment, and can feel in control when BV recurs.

## Summary

Bacterial vaginosis (BV) is highly prevalent among women of childbearing age; affecting between 5% and 50% of women in various populations. The symptoms can cause considerable distress, particularly in those most frequently and severely affected.

Debate continues as to whether it is a sexually transmitted condition or merely associated with intercourse and other infections. The recent description of a biofilm in which *Gardnerella vaginalis* and *Atopobium vaginae* predominate has again placed *Gardnerella* at the center of pathogenesis, and it may be that particular pathogenic strains are sexually transmitted.

BV is associated with infections following termination of pregnancy and other gynecological procedures. It is associated with STIs such as chlamydia and gonorrhoea, and is a risk factor for acquisition of HIV in women. In pregnancy, it is a risk factor for late miscarriage, idiopathic preterm birth, and post-caesarean section endometritis.

Oral metronidazole remains the mainstay of treatment; metronidazole and clindamycin vaginal treatments also available. Prevention of recurrent BV remains problematic, with limited benefit from alternative treatments with lactic acid gel or probiotics. Studies of antibiotics in pregnancy have yielded conflicting results, and routine screening and treatment with antibiotics is not recommended.

It is hoped that improved understanding of the pathogenesis of BV arising from studying biofilms and typing *Gardnerella* with molecular methods will lead to improved treatments and outcomes.

## Pelvic Inflammatory Disease

Jonathan D.C. Ross

### Introduction

Pelvic inflammatory disease (PID) is inflammation of the endometrium, uterus, fallopian tubes, and adnexal structures, which usually occurs secondary to sexually transmitted infections of the lower genital tract. This differs slightly from “pelvic infection” which includes not only PID but also puerperal sepsis, post-abortion infections, and local pelvic infection secondary to surgery. PID is a common condition in young women and extremely costly,<sup>1</sup> both in financial terms and also due to the considerable physical and psychological morbidity that can follow.

### History

The two great Scottish venereologists of the 18<sup>th</sup> century, John Hunter (1728–1793) and Benjamin Bell (1749–1805), had conflicting opinions about the link between gonorrhea and PID—Hunter stating that “it has been asserted that the ovaria are sometimes affected ... I should very much doubt the possibility” but Bell correctly concluding that “In some cases the inflammation [from gonorrhea] spreads to ... the uterus and ovaria.”<sup>2</sup> Bell’s opinions were not widely accepted, however, and 100 years later, it was still generally believed that pelvic inflammation occurred secondary to obstruction of the lochia, uterine malposition, trauma, and/or excessive intercourse.<sup>2</sup>

Emil Noeggerath (1827–1894), German born but holding a chair in obstetrics and gynecology in New York, presented data from a large clinical cohort of women, suggesting that latent gonorrhea and associated PID were extremely common affecting up to two-thirds of the urban US population.<sup>3</sup> This proposal was met with anger and disbelief by his colleagues in the US and abroad, who felt that its implications on the moral standards of the general population were scandalous and unacceptable. The identification of the gonococcus in 1879 by Neisser vindicated Noeggerath but he died a broken man in 1894. The association of PID with gonorrhea and TB was thus recognized by the mid 19<sup>th</sup> century but it was another 100 years until the polymicrobial

nature of the infection became clear and the central role of *Chlamydia trachomatis* identified.

### Biology

Many organisms can be isolated from the upper genital tract of women with PID, often concurrently, but it remains unclear which are primary pathogens (Table 45.1). It is also difficult to make direct comparisons among bacterial flora isolated in different clinical studies because of differences in how samples were collected and analyzed. The best epidemiological and clinical evidence supports the role of sexually acquired *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, ascending from the endocervix to the endometrium and fallopian tubes. However, in 20–70% of PID, no organism will be isolated from the upper genital tract.<sup>4</sup> This may reflect clearance of an initial chlamydial or gonococcal infection secondary to the infected tissues becoming increasingly anaerobic, and/or involvement of as yet unidentified agents.

**Table 45.1:** Organisms Associated with Pelvic Inflammatory Disease

Aerobic	Anaerobic
<i>Neisseria gonorrhoeae</i>	<i>Bacteroides</i> sp.
<i>Chlamydia trachomatis</i>	<i>Peptostreptococcus</i> sp.
<i>Mycoplasma genitalium</i>	<i>Clostridium bifermentans</i>
<i>Gardnerella vaginalis</i>	<i>Fusobacterium</i> sp.
<i>Strep. pyogenes</i>	
Coagulase negative staphylococci	
<i>Escherichia coli</i>	
<i>Haemophilus influenzae</i>	
<i>Strep. pneumoniae</i>	
<i>Mycobacterium tuberculosis</i>	
<i>Ureaplasma urealyticum</i>	

## NEISSERIA GONORRHOEAE

*N. gonorrhoeae* can be isolated from the fallopian tubes in women with PID<sup>5,6</sup> and between 8% to 19% of those with cervical gonorrhea have signs of upper genital tract infection.<sup>7,8</sup> The absence of *N. gonorrhoeae* from the lower genital tract cannot exclude gonococcal PID, since it may only be isolated from the upper genital tract in some women.<sup>6</sup>

Certain subtypes of gonococci are particularly associated with PID including the AHU-auxotype and strains which are more resistant to antibiotics.<sup>9</sup> A number of virulence factors have also been identified, including the expression of pili on the surface membrane of the bacteria, which are involved in attachment to the host epithelial cells.<sup>10</sup>

## CHLAMYDIA TRACHOMATIS

*C. trachomatis* is an unusual bacterium because it requires the host cell structures to replicate and is therefore an obligate intracellular bacterium. This leads to potential difficulties in confirming the diagnosis because culture is only possible following inoculation of cell lines and chlamydia enzyme-linked immunoassays are insensitive. Nucleic acid amplification tests (NAATs) are, however, widely available and provide a rapid and sensitive alternative.

The role of *C. trachomatis* in the pathogenesis of PID is supported by the detection of the organism in the upper genital tract of women with clinical symptoms and signs of PID,<sup>11,12</sup> the high prevalence of anti-chlamydial antibodies in women with tubal obstruction,<sup>13</sup> and animal data demonstrating salpingitis after inoculation with *C. trachomatis*.<sup>14</sup> The concept of canalicular spread of infection from lower to upper genital tract, as opposed to hematogenous, lymphatic, or trans-peritoneal spread, is supported by studies in monkeys showing protection against salpingitis in those animals with ligated fallopian tubes.<sup>15</sup> The risk of developing PID in young women with lower genital tract chlamydia infection is approximately 10%.<sup>16</sup>

## MYCOBACTERIUM TUBERCULOSIS

A significant cause of PID in Western countries in the past, tuberculous PID is now largely confined to developing countries or immigrants from these countries.<sup>3</sup> Most cases occur secondary to an extra-genital infection but rare instances of sexual transmission can also occur.<sup>15</sup> *M. tuberculosis* is not usually isolated from the lower genital tract<sup>17</sup> and samples should be taken by uterine curettage, or via laparoscopy, for culture or PCR analysis to make a diagnosis. Chest x-ray, sputum culture, and early-morning urine samples for culture are also appropriate. Quadruple anti-tuberculous chemotherapy is effective, e.g., isoniazid, rifampicin, ethambutol, and pyrazinamide, but extensive pelvic involvement or fibrosis may require surgery.

## OTHER ORGANISMS

PID in the absence of *N. gonorrhoeae* or *C. trachomatis* is associated with more prolonged and recurrent disease.<sup>18</sup>

## Mycoplasma genitalium

*M. genitalium* is a common cause of sexually acquired urethritis in men and has been associated with cervicitis, endometritis, and salpingitis in women.<sup>19,20</sup> Direct inoculation of the organism in the lower genital tract of non-human primates causes salpingitis and oophoritis,<sup>21,22</sup> and women with tubal factor infertility are more likely to have immunological evidence of previous *M. genitalium* infection.<sup>23</sup> There is also a trend toward more adverse long-term sequel in women with PID in whom *M. genitalium* is detected.<sup>24</sup>

## Anaerobes

Laboratory evidence and animal studies suggest that anaerobes are important pathogens in PID and identify them as a specific target for treatment.<sup>25,26</sup> In the lower genital tract, the production of mucinases and sialidases<sup>27</sup> by anaerobes may facilitate the passage of bacteria through the cervical mucus plug leading to upper genital tract infection. Anaerobes can be found in the genital tract of 13% to 78% women with PID<sup>28</sup> and are associated with more severe disease, including abscess formation.<sup>29,30</sup> The presence of a wide variety of organisms have been reported including *Bacteroides fragilis*, peptostreptococci, and peptococci.<sup>31</sup>

## Association with Bacterial Vaginosis

An association with bacterial vaginosis (BV) is suggested by the higher rate of BV in women with PID,<sup>32–34</sup> and the similarity in organisms was found between the upper genital tract in PID and lower genital tract in bacterial vaginosis.<sup>35</sup> Also, treating BV appears to reduce the risk of PID in women presenting for termination of pregnancy.<sup>36</sup> Prospective studies have failed to find a direct causal link between BV and PID, but women with concurrent BV and gonorrhea or chlamydia, or those who have large numbers of anaerobic gram-negative bacteria in the vagina, do appear to be at increased risk of developing PID.<sup>37</sup>

## Actinomyces

Pelvic infection with *Actinomyces israeli* has been associated with intrauterine device (IUD) use but IUD removal and antibiotic therapy are only indicated when the woman has symptoms, which may include intermenstrual bleeding, pelvic pain, or vaginal discharge.<sup>38</sup>

## ADDITIONAL POTENTIAL PATHOGENS

*Mycoplasma hominis*, *Ureaplasma urealyticum*, and other bacteria have been isolated from the upper genital tract, but whether they represent true pathogens or are markers of sexual activity is not known.<sup>15,39</sup> It is also possible that viruses may account for some cases where bacterial culture is negative, e.g., coxsackie, echo, herpes simplex.<sup>15,40,41</sup> In a small number of cases, respiratory bacteria, such as *H. influenzae* and *Strep. pneumoniae*, are isolated suggesting a possible link with orogenital sexual contact.

## Epidemiology

PID is one of the commonest causes of morbidity in young women and affects approximately 1 million women each year in the US.<sup>1</sup> If cases presenting in the community are included, the prevalence is even higher—estimated at over 1 in 60 women of reproductive age in England and Wales.<sup>42</sup> Trends in PID rates parallel those of gonorrhea and chlamydia<sup>43</sup> (Fig. 45.1), but lag behind by several months as can be seen in the increasing rates of PID in the UK in 1970s and 1980s<sup>44,45</sup> and decreasing rates in the US in the 1990s.<sup>46</sup>

The peak incidence of PID is between the ages of 15 and 25 years.<sup>46</sup> Those communities which have a large young population are therefore at particular risk, including developing countries. This increased risk is related to both high-risk sexual behavior in this age group, and probably also greater susceptibility to PID secondary to cervical ectopy, more penetrable cervical mucous, and lower levels of anti-chlamydial antibodies. Since not all women develop PID following lower genital tract infection, it is likely that susceptibility is also genetically determined and an association with HLA-A31 has been described.<sup>47</sup>

Not surprisingly, some of the risk factors for PID are similar to those for chlamydia and gonorrhea:

- multiple sexual partners
- a past history of sexually transmitted disease in the patients or their partner
- lack of condom use.<sup>48</sup>

Other risk factors seem to be linked to the spread of infection from the lower to the upper genital tract:

- douching is more commonly reported in women with PID,<sup>49,50</sup> particularly in certain ethnic sub-groups, e.g., black American women.<sup>51</sup> However, prospective studies have failed to confirm that douching causes PID<sup>52,53</sup> and it is likely that the vaginal discharge that is associated with PID may itself lead to increased douching.
- the oral contraceptive pill appears to reduce the risk of infection ascending into the upper genital tract and causing PID,<sup>54,55</sup> although the benefit may be limited to women with *C. trachomatis* infection and symptomatic PID.<sup>56</sup> The effect is probably mediated by progesterone-induced changes in the cervical mucous barrier and endometrial suppression, and/or a direct steroid effect reducing immune-related damage to the tubal mucosa.<sup>57,58</sup>
- use of non-progesterone IUD is associated with increased risk of PID but probably only for the initial few months after insertion<sup>59</sup> with the absolute risk thereafter being low. This risk can therefore be reduced considerably by appropriate screening and treatment of lower genital tract infections prior to IUD insertion.
- frequency of sexual intercourse in monogamous women,<sup>48</sup> although this may be limited to women with pre-existing bacterial vaginosis.<sup>60</sup>
- smoking increases the risk of PID by 1.7–2.3 fold<sup>61</sup> and, in one study, the more cigarettes smoked the higher the risk,<sup>62</sup> although the mechanism is unclear.

Fig. 45.1: Incidence of PID in genitourinary medicine clinics in England and Wales.

In addition, any operative procedure involving instrumentation of the cervical os has the potential to introduce infection into the upper genital tract, including termination of pregnancy,<sup>36</sup> hysterosalpingography, or *in vitro* fertilization.<sup>63,64</sup> Postpartum pelvic infection secondary to gonorrhea and chlamydia can occur and may be a particular problem in developing countries.<sup>65</sup>

Reported rates of PID in developing countries appear to be higher than in Western Europe and the US. In India and Pakistan, 9% to 19% of young women have been reported to have PID in community studies,<sup>66–68</sup> and the association with sexually transmitted diseases, such as gonorrhea and chlamydia, may be less strong in these countries.<sup>69,70</sup> A strong association has been noted with intrauterine contraceptive use<sup>67,68</sup> and access to care may also be a problem in some areas.<sup>66</sup> Elsewhere, rates of PID in gynecology inpatients vary from 7% in Egypt and 6% in Cuba to 17% to 40% in Africa, and 15% to 37% in Southeast Asia.<sup>71</sup> This is also reflected in high rates of infertility—approaching 50% in some areas of sub-Saharan Africa.<sup>71</sup>

## Pathology

PID is the result of organisms ascending from the mucosa of the vagina and cervix, via the endometrium, to the fallopian tubes and adnexae.<sup>15,72</sup> An active transport mechanism can move spermatozoa, dyes, and bacteria from the vagina to the upper genital tract<sup>73</sup> but it remains unclear what additional factors are required for PID to develop, although the loss of the cervical mucous plug during menstruation is probably also important. In addition, movement of bacteria to the upper genital tract may be facilitated by their attachment to either trichomonads or spermatozoa.

The endometritis associated with PID comprises a plasma cell infiltrate with polymorphonuclear cells and the formation of lymphoid follicles. In the upper genital tract, there is an initial acute inflammatory response, usually affecting both the fallopian tubes to some degree, with macroscopic swelling and erythema. An inflammatory exudate may build up within the fallopian tube, mixed with blood and necrotic epithelial cells, and lead to tubal obstruction. As subsequent healing occurs, adhesions form which can permanently block the tube, and chronic inflammation may result in a pyosalpinx or hydrosalpinx if the tube becomes blocked. Alternatively, the tube may remain patent but become chronically fibrosed and thickened with the invasion of mononuclear cells and formation of lymphoid follicles.

## CHLAMYDIA TRACHOMATIS

*C. trachomatis* invades both the ciliated and non-ciliated epithelial cells of the fallopian tube before replicating within an intracellular vacuole and releasing new infectious particles into the tube lumen.<sup>74</sup> Much of the inflammatory response to *C. trachomatis* is secondary to a delayed hypersensitivity reaction to a chlamydial heat shock protein rather than direct damage from bacterial invasion itself.<sup>75,76</sup> An associated Th1-type T cell

response initially occurs with the production of gamma interferon and interleukins 2, 6, and 10,<sup>77</sup> and histologically, a low-grade lymphocytic response is evident in the tissues.

## NEISSERIA GONORRHOEAE

Unlike *C. trachomatis*, *N. gonorrhoeae* initially primarily infects the non-ciliated cells with the production of tumor necrosis factor and gamma interferon, leading to collateral damage to the adjacent ciliated cells.<sup>78–80</sup> Following entry into epithelial cells, *N. gonorrhoeae* pass through the cytoplasm and basal cell surface to invade the submucosa<sup>81</sup> with an associated acute neutrophil response.

## Immunology

Re-infection with *N. gonorrhoeae* is frequently seen but some degree of strain-specific immune protection may occur, which reduces the risk of repeated upper genital tract involvement.<sup>8,82</sup> The intense immune-mediated response to upper genital tract infection seen with *N. gonorrhoeae* may be responsible for the decreasing isolation rates of the organism with increasing duration of symptoms.<sup>83</sup> This contrasts with recurrent infection with *C. trachomatis* where the immune response to infection is generally milder.<sup>4</sup> After priming by an initial episode of chlamydial PID, there is an increase in tubal damage if re-infection occurs,<sup>84</sup> possibly mediated by a cross-reaction between chlamydial heat shock protein 60 (hsp60) and human hsp60.<sup>85</sup>

## Clinical Features

PID may be symptomatic or asymptomatic and, even when present, clinical symptoms and signs lack sensitivity and specificity (the positive predictive value of a clinical diagnosis is 65% to 90% when compared to a laparoscopic diagnosis).<sup>6,86–88</sup> It also appears that some women with laparoscopic evidence of fallopian tube inflammation have symptoms, such as lower abdominal pain or intermenstrual bleeding, which are not initially recognized as being due to PID.<sup>89</sup>

The following features are suggestive of a diagnosis of PID, and the more features that are present the greater the likelihood of the diagnosis<sup>6,86,87,90</sup>:

- lower abdominal pain—usually bilateral and which may be worse on movement
- dyspareunia
- abnormal bleeding (irregular, heavy, or painful)—usually as a result of endometritis or cervicitis
- abnormal vaginal or cervical discharge
- lower abdominal tenderness, possibly with guarding
- adnexal tenderness on bimanual vaginal examination (high sensitivity but poor specificity<sup>91,92</sup>)—an inflammatory mass may be palpable (less sensitive but more specific<sup>91</sup>)
- cervical motion tenderness on bimanual vaginal examination (also known as cervical excitation)
- fever (>38°C)

- severe infection is associated with systemic symptoms such as malaise, fever, and vomiting.

It has been suggested that certain clinical criteria should be present in order for a diagnosis of PID to be made, e.g., abdominal tenderness plus cervical excitation plus adnexal tenderness. Although the presence of multiple clinical signs increases the likelihood of PID, the majority of cases are atypical or asymptomatic and a high index of suspicion is required since delayed treatment is associated with a higher rate of complications.<sup>93</sup> Gonococcal PID is associated with a shorter history of symptoms (<3 days) than chlamydial PID (>1 week)<sup>60</sup> and is clinically more severe<sup>4</sup> with a higher incidence of pyrexia and a palpable adnexal mass.<sup>4</sup>

The Fitz–Hugh–Curtis syndrome may complicate PID and comprises right upper quadrant pain and tenderness secondary to perihepatitis, which occurs in 10% to 20% of women with PID.<sup>94,95</sup> On examination, a hepatic friction rub is occasionally present. Sometimes, perihepatitis dominates the clinical picture and can be mistaken for acute cholecystitis. The Fitz–Hugh–Curtis syndrome may occur secondary to either chlamydial or gonococcal PID,<sup>96,97</sup> can be associated with abnormal liver function tests, and on laparoscopy, adhesions between the liver capsule and the overlying peritoneum are sometimes present.<sup>98</sup>

## Prognosis and Sequelae

Deaths due to PID are fortunately rare in industrialized countries<sup>99</sup> but short- and long-term complications are common. Untreated PID can progress rapidly (within days) to cause chronic inflammation, fibrosis, and tubal damage, resulting in chronic pain, infertility, and ectopic pregnancy. The risk of sequelae is increased with:

- delay in diagnosis and starting antibiotic therapy. Women waiting more than 3 days after the onset of abdominal pain have a three-fold increased risk of impaired fertility<sup>93</sup> which is most marked for chlamydial PID.
- severity of salpingitis as assessed at initial laparoscopy.<sup>43,100</sup>
- a second or subsequent episode of PID carries a much worse prognosis than the initial episode<sup>14,84,101,102</sup> (Fig. 45.2).
- not using the oral contraceptive, particularly for chlamydial PID.<sup>56</sup>
- non-gonococcal PID.<sup>84,103</sup>
- advanced age, in women with two or more episodes of PID.<sup>84</sup>

## TUBO-OVARIAN ABSCESS

Usually occurring as a late feature, abscess formation is associated with anaerobic infection.<sup>30,31</sup> Patients classically present with fever, malaise, and a tender adnexal mass, but clinical examination is unreliable. When the diagnosis is suspected, ultrasound scanning can be used to identify an abscess and assess the response to antibiotic treatment. If a rapid reduction in size is not evident over 72 hours or if the abscess is large (greater than 8-cm diameter), surgical drainage is usually required.

## CHRONIC PELVIC PAIN

Adhesions can form within the pelvis following the acute inflammation of PID and are associated with symptoms of chronic pelvic pain, but severe pelvic pain can also occur in the absence of adhesions.<sup>104</sup> Chronic pelvic pain (lasting over 6 months) has been reported in 18% to 40% of women following PID.<sup>84,105–107</sup> Smaller series have found pelvic pain in more than half their patients<sup>39</sup> and the risk of chronic pain increases with the number of PID episodes. In developing countries, PID remains a common cause of pelvic pain—16% of cases in one series in Pakistan<sup>108</sup> and 31% in Mexico.<sup>109</sup>

Repeat courses of antibiotics are not helpful after the initial treatment of acute PID, suggesting that chronic pelvic infection is uncommon. Appropriate analgesia should be given and other pelvic pathologies excluded. Surgical intervention to divide adhesions is of limited value unless they are extensive,<sup>110</sup> but hysterectomy may be required for those with intractable pain.

## INFERTILITY

PID accounts for between a quarter and two-third of cases of infertility,<sup>111</sup> the higher proportion being seen in developing countries. The presence of antibodies to *C. trachomatis*, as a marker of past infection, is strongly associated with tubal infertility<sup>13</sup> but there is often no history of clinical PID suggesting that pelvic inflammation sufficiently severe to cause tubal damage often remains subclinical. The risk of infertility increases with each episode of PID—13% for an initial episode rising to 75% following 3 episodes of infection<sup>84</sup> (Fig. 45.2).

Surgical intervention to restore tubal patency has limited success possibly because the ciliated tubal epithelium, which plays an important role in transporting the ovum through the fallopian tube, remains damaged. *In vitro* fertilization provides an alternative when available. Although PID can reduce the chance of becoming pregnant, there is no subsequent increased risk of preterm delivery, stillbirth, or abortion.<sup>84</sup>

**Fig. 45.2:** Risk of infertility with tubal occlusion following PID.<sup>84</sup>

## ECTOPIC PREGNANCY

Chlamydial PID increases the relative risk of ectopic pregnancy by 2.4 to 7.9<sup>112,113</sup> with reported rates of 1% to 4%.<sup>84,106,114</sup> Some care needs to be taken in using ectopic pregnancy as a surrogate marker of PID prevalence because changes in IUD use, improved diagnosis, and an aging population of women attempting to get pregnant may all influence ectopic pregnancy rates.

## Diagnosis

As has already been highlighted, the clinical diagnosis of PID is insensitive and non-specific. Unfortunately, there is no “gold standard” test which will detect all cases of PID and a low threshold for starting antibiotic treatment is therefore required.

Laparoscopy may strongly support a diagnosis of PID<sup>32</sup> but is not justified routinely on the basis of cost, morbidity, and the potential difficulty in identifying mild intra-tubal inflammation or endometritis.<sup>6,32,86,87</sup> Laparoscopic findings are subjective and open to inter- and intra-observer variation—repeating the laparoscopy may detect abnormalities not visible at the initial procedure.<sup>6</sup> It may be particularly valuable in patients with systemic symptoms if the diagnosis is in doubt or if there is no response to antibiotics within 72 hours.

Ultrasound scanning may be useful to detect tubal abscesses<sup>115</sup> and transvaginal scanning may be sensitive enough to detect tubal changes associated with endometritis,<sup>116</sup> but diagnostic sensitivity will be dependent on the experience of the operator, and at present, routine use is not justified. Newer ultrasound techniques, including power Doppler imaging, may increase sensitivity by detecting the hyperemia associated with inflammation and permit the diagnosis of salpingitis.<sup>117</sup>

Endometritis is often associated with PID<sup>32</sup> and may correlate with its severity but endometrial inflammation is also frequently seen in women who have cervical infection without evidence of PID<sup>118</sup> and the distribution of changes in the endometrium may be patchy. The role of endometrial sampling in the diagnosis of PID is therefore unclear.

Laboratory markers may be of limited value—an elevated erythrocyte sedimentation rate or C-reactive protein support the diagnosis and correlate with the severity of PID<sup>119</sup> but are not specific to PID. An increase in the white blood count occurs in up to two-thirds of patients with PID but is also seen in many patients without PID, and tends to be within normal limits when PID is mild.<sup>88</sup> Culdocentesis (sampling from the pouch of Douglas) can be misleading since organisms present at this site are not necessarily also detectable from the fallopian tubes,<sup>120</sup> although an increased number of inflammatory cells in a culdocentesis sample does give some support to a diagnosis of PID.

## DIFFERENTIAL DIAGNOSIS

A number of other conditions need to be excluded in a young woman presenting with pelvic symptoms (Table 45.2).

**Table 45.2:** Main Differential Diagnosis of PID

Gynecological	Ectopic pregnancy
	Torsion/rupture/hemorrhage of ovarian cyst
	Endometriosis
Gastrointestinal	Appendicitis
	Irritable bowel syndrome
	Inflammatory bowel disease
Miscellaneous	Functional pain
	Pelvic adhesions secondary to previous pelvic pathology

## Ectopic Pregnancy

This is more likely if there is a history of amenorrhea followed by initial unilateral pain. It is advisable to perform a pregnancy test on all women with lower abdominal pain because of the severe consequences of a missed or delayed diagnosis of ectopic pregnancy. An ultrasound scan should be performed if the diagnosis remains in doubt.

## Bowel Pathology

Appendicitis is a relatively common cause of abdominal pain in young women. Classically, there is a history of central abdominal pain becoming localized to the right iliac fossa and associated with vomiting and diarrhea. Irritable bowel syndrome is also common in young women and inflammatory bowel disease can occur in this age group. The presence of colicky pain (which may be relieved on defecation), diarrhea, and/or constipation may suggest a gastrointestinal cause.

## Ovarian Pathology

Torsion, bleeding, or rupture of an ovarian cyst may result in pain and pelvic peritonism with a similar presentation to PID. A pelvic mass may be present and difficult to differentiate from a tubo-ovarian abscess. The onset of symptoms is usually unilateral, and more acute and severe than in patients with PID.

## Endometriosis

Endometriosis is less likely to cause fever than acute PID, and bacteriological cultures are usually negative, although both conditions can co-exist. The history is often chronic over many weeks or months and symptoms may be related to menstruation.

## Microbiology

Taking samples from the fallopian tubes, although desirable, is not usually practical but testing for gonorrhea and chlamydia in the lower genital tract is recommended since a positive result supports the diagnosis of PID. However, the absence of infection at this site does not exclude PID.<sup>6,86,87</sup>

Appropriate screening tests include:

- endocervical and urethral microscopy and culture for gonorrhea—samples should also be taken from the rectum and throat if the history indicates that these sites may have been exposed to infection. Increasingly nucleic acid amplification tests (NAATs) are providing an alternative to gonococcal culture and can be performed on non-invasive samples such as self-taken vulval swabs.
- endocervical samples for NAAT chlamydia tests (culture and enzyme-linked immunoassay testing are significantly less sensitive)—urine or vulval swabs can also be used with NAAT chlamydia tests.
- consider screening for other sexually acquired infections such as trichomoniasis, syphilis, HIV, chancroid, and lymphogranuloma venereum, depending on the local prevalence, clinical history, and availability of laboratory tests.

## Serology

Up to 59% of women with chlamydial PID will develop an antibody response and higher antibody levels may be associated with more severe disease,<sup>121</sup> but lack of specificity (in particular cross-reaction with *C. pneumoniae*) and the delay in the appearance of antibodies limit the usefulness of serology in making a diagnosis.

## Treatment

Broad-spectrum antibiotic therapy is required to cover *N. gonorrhoeae*, *C. trachomatis*, and anaerobic infection.<sup>6,86,122</sup> Good-quality evidence of the long-term effectiveness of therapy in preventing the complications of PID is currently lacking and there are comparatively fewer data on oral than parenteral regimens. The choice of an appropriate treatment regimen may be influenced by:

- Knowledge of local antimicrobial sensitivity patterns

Antibiotic resistance is very unlikely for *C. trachomatis* but knowledge of local patterns of resistance to *N. gonorrhoeae* may guide the initial choice of therapy. If more than 5% of local isolates are resistant, then the choice of empirical antibiotics should be reviewed.

- Cost

There is little evidence that any one of the regimens recommended below has superior efficacy compared to the others; therefore, it may be appropriate for cost to influence the choice of antibiotics.

- Patient factors

Choosing a regimen with once or twice daily dosing, small pill burden, and few side-effects to improve acceptability and adherence is of particular relevance for outpatient therapy. A history of allergy,

renal or hepatic impairment, and interactions with other concurrent therapy may influence the choice of antibiotics.

- Severity of disease

For patients who have more severe systemic manifestations of PID parenteral therapy as an inpatient may achieve higher tissue levels of antibiotics and permit close monitoring. It remains unclear if it improves the prospect of preserving fertility.

- General advice

Rest is advised for those with severe disease and appropriate analgesia should be provided. If there is a possibility that the patient could be pregnant, a pregnancy test should be performed.

Patients should be advised to avoid unprotected intercourse until they, and their partner(s), have completed treatment and follow-up, and all patients should be offered screening for other sexually transmitted infections. A detailed explanation of their condition with particular emphasis on the long-term implications for their health and of their partner(s) should be provided, reinforced with clear and accurate written information.

## CRITERIA FOR INPATIENT MANAGEMENT

Admission for parenteral therapy, observation, further investigation, and/or possible surgical intervention should be considered in the following situations<sup>86,123</sup>:

- severe symptoms or signs
- presence of a tubo-ovarian abscess
- pregnancy
- inability to tolerate an oral regimen
- lack of response or intolerance to oral therapy

## TREATMENT REGIMENS

Evidence-based antibiotic regimens are available but direct comparisons of different treatments need to be interpreted with caution since there is little standardization between clinical trials for assessing diagnosis and measuring outcomes. It is recommended that for inpatient management, intravenous therapy should be continued until 24 hours after clinical improvement and then switched to oral. Dosage recommendations may need to be adjusted slightly, depending on local licensing regulations and the availability of drug formulations.

## Outpatient Regimens

- Oral ofloxacin 400 mg twice daily plus oral metronidazole\* 500 mg twice daily for 14 days.<sup>100,124–127</sup> A single dose of IM ceftriaxone 250 mg should be added in areas with a high prevalence of quinolone-resistant *N. gonorrhoeae*.
- IM ceftriaxone 250 mg single dose (or IM cefoxitin 2 g single dose with oral probenecid 1 g) followed by oral doxycycline 100 mg twice daily plus metronidazole\* 400 mg twice daily for 14 days.<sup>122</sup>

\*Metronidazole may be omitted if patients have clinically mild disease (with less likelihood of anaerobic infection) and are suffering from gastrointestinal side effects.

- Oral moxifloxacin 400 mg once daily for 14 days.<sup>128,129</sup> A single dose of IM ceftriaxone 250 mg should be added in areas with a high prevalence of quinolone-resistant *N. gonorrhoeae*.

## Inpatient Regimens

- Intravenous cefoxitin 2 g four times daily (or IV cefotetan 2 g twice daily) plus IV doxycycline 100 mg twice daily (oral doxycycline may be used if tolerated or if IV doxycycline is not available) followed by oral doxycycline 100 mg twice daily plus oral metronidazole 400 mg twice daily for a total of 14 days.<sup>86,122,124,130,131</sup>
- Intravenous clindamycin 900 mg three times daily plus IV gentamicin (2 mg/kg loading dose followed by 1.5 mg/kg three times daily [a single daily dose may be substituted]) followed by either oral clindamycin 450 mg four times daily or oral doxycycline 100 mg twice daily plus oral metronidazole 400 mg twice daily to complete 14 days.<sup>86,122,130,131</sup>
- Intravenous ofloxacin 400 mg twice daily plus IV metronidazole 500 mg three times daily for 14 days.<sup>86,124,130</sup> IV cefoxitin 2 g four times daily should be added in areas with a high prevalence of quinolone-resistant *N. gonorrhoeae*.
- Intravenous ciprofloxacin 200 mg twice daily plus IV (or oral) doxycycline 100 mg twice daily plus IV metronidazole 500 mg three times daily.<sup>86,124,132</sup> IV cefoxitin 2 g four times daily should be added in areas with a high prevalence of quinolone-resistant *N. gonorrhoeae*.

Where the above regimens are not available, antibiotic therapy should be given for 14 days in an attempt to cover:

- *Neisseria gonorrhoeae*, e.g., cephalosporins, quinolones (if locally sensitive), penicillin (if locally sensitive).
- *Chlamydia trachomatis*, e.g., tetracyclines, macrolides.
- anaerobic bacteria, e.g., metronidazole.

Review at 72 hours is recommended,<sup>86</sup> particularly for those with a moderate or severe clinical presentation, and should show a substantial improvement in clinical symptoms and signs. Failure to do so suggests the need for further investigation, parenteral therapy, and/or surgical intervention.

## ACTINOMYCES-ASSOCIATED PID

Pelvic actinomycosis is extremely rare but actinomyces organisms may be found in the female genital tract as a commensal, particularly in women with an IUD.

For women who have actinomyces-like organisms identified on a cervical smear when an IUD is *in situ*, the following approach is suggested<sup>133</sup>:

- if asymptomatic, the IUD may be left in place and the woman advised to return if symptoms occur.
- if symptomatic, the IUD should be removed and sent for culture of actinomyces (a cervical swab is not an appropriate specimen to detect actinomyces infection). No further treatment is generally required and an IUD may be reinserted if required.

If treatment is required in a persistently symptomatic woman, then amoxicillin 3 g daily in divided doses for at least 14 days combined with metronidazole can be used.

## MANAGEMENT OF PARTNERS

The current male partners of women with PID should be contacted and offered health advice and screening for gonorrhea and chlamydia. Other recent sexual partners may also be offered screening with contacts over a 6-month period being sought, although this time period may be influenced by the sexual history. Partners identified in this way should be advised to avoid intercourse until they and the index patient both have completed a course of treatment. Gonorrhea diagnosed in the male partner should be treated appropriately and concurrently with the index patient. Concurrent empirical treatment for chlamydia is recommended for all sexual contacts due to the variable sensitivity of currently available diagnostic tests. If adequate screening for gonorrhea and chlamydia in the sexual partner(s) is not possible, empirical therapy for gonorrhea and chlamydia should be given.

A further review 4 weeks after therapy may be useful to ensure:

- an adequate clinical response to treatment.
- a full course of antibiotics was completed.
- all relevant sexual contacts have been approached for screening and treatment.

Repeat testing for gonorrhea and chlamydia may be appropriate in those in whom persisting symptoms, compliance with antibiotics, antibiotic resistance pattern, and/or tracing of sexual contacts indicate the possibility of persisting or recurrent infection.

## SPECIAL SITUATIONS

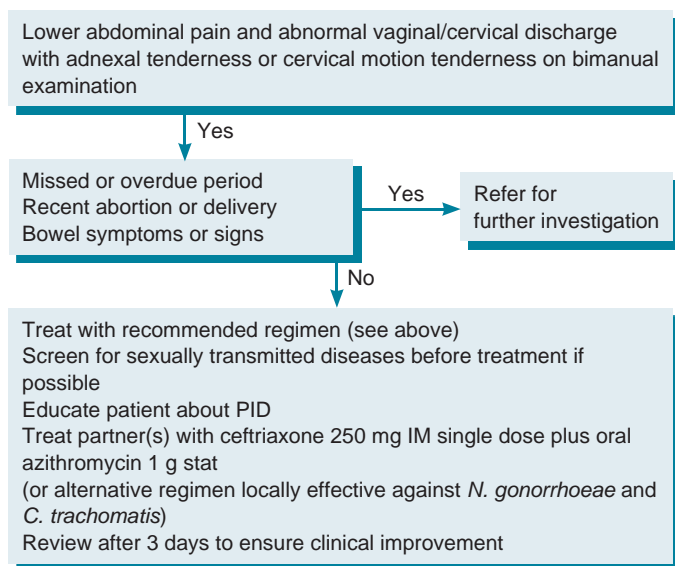

### Intrauterine Device

Two retrospective studies<sup>134,135</sup> and a small prospective clinical trial<sup>136</sup> have shown no difference in short-term outcomes following removal of an IUD in women with PID, but a more recent large prospective trial has reported a significant clinical benefit when the IUD is removed.<sup>137</sup> A small number of fatalities have also been associated with IUD use.<sup>138</sup> Removal of the IUD should therefore be considered, especially in women with moderate-to-severe disease. The prophylactic use of antibiotics to prevent the introduction of infection into the upper genital tract during IUD insertion has not been found to be effective.<sup>139</sup>

## SYNDROMIC MANAGEMENT

When medical support services are limited, a syndromic approach to management may be required. Figure 45.3 summarizes how such a patient should be managed.

**Fig. 45.3:** Syndromic management of PID.

## Prevention

### PRIMARY PREVENTION

Screening high-risk women for chlamydia infection and providing appropriate treatment are associated with a reduction in PID of more than 50% women.<sup>140</sup> The use of barrier contraception can also be effective and reduces the risk of PID by about 40%.<sup>141</sup>

In women undergoing surgical procedures that increase the risk of introducing infection into the upper genital tract, antibiotic prophylaxis should be considered if screening for sexually transmitted infections has not been performed, e.g., termination of pregnancy, hysterosalpingography, dilatation, and curettage. There is little data on which to base the choice of which antibiotics to use but cover for *N. gonorrhoeae*, *C. trachomatis*, and anaerobes, based on local sensitivity patterns, is desirable.

### SECONDARY PREVENTION

Since the risk of sequel is significantly higher with recurrent PID, appropriate health education, tracing of sexual contacts, and screening of those at risk are desirable.

## Introduction

The term “mycoplasmas” is commonly used as the trivial name for members of the class Mollicutes (from Greek *mollis*, soft; *cutis*, skin, i.e., the “soft-skinned”). They are the smallest free-living bacteria but lack the rigid cell wall of other bacteria, making them resistant to penicillins and related antimicrobials. Instead, they have a flexible trilaminar unit membrane enclosing the cytoplasm. Mycoplasmas are usually 0.4–0.5  $\mu$  but viable cells, even smaller than 0.3  $\mu$ , are not unusual. The small size and flexible membrane enable them to pass through filters with pore-sizes as small as 0.2  $\mu$ , which are generally believed to retain all bacteria. The filterability and lack of formation of a cell wall after incubation in medium without antibiotics has now become one of the key properties defining new species as mycoplasmas.<sup>1,2</sup> The mycoplasmas isolated commonly from humans belong to the order Mycoplasmatales and family Mycoplasmataceae containing two genera: *Mycoplasma* and *Ureaplasma*. The genus *Mycoplasma* contains more than 100 species, of which 16 at present are considered a part of the human flora. *M. hominis* and *M. genitalium* are the two mycoplasma species most often found in the urogenital tract. Two ureaplasma species *U. urealyticum* and *U. parvum* (previously known as *U. urealyticum*, parvo biovar) are commonly found in the human urogenital tract. Ureaplasmas uniquely hydrolyze urea and were originally termed T-strains or T-mycoplasmas because of the tiny (T) colonies (15–60  $\mu$ m diameter) they form on agar medium,<sup>3</sup> in contrast to the larger (90  $\mu$ m or more diameter) characteristic ‘fried-egg’-like colonies produced by most other mycoplasmas.

The small size of the mycoplasma genome (as little as 580 kbp for *M. genitalium*<sup>4</sup>) restricts metabolic capabilities, making culture of some mycoplasmas difficult or impossible. Despite their general similarity, mycoplasmas form a heterogeneous group with differing host specificities, nutritional requirements, metabolic reactions, and DNA and antigenic composition. They are believed to have evolved from gram-positive bacteria most closely related to the clostridia by degenerative evolution leading to genomic reduction.<sup>5</sup> Mycoplasmas, particularly species with the smallest genomes, have high mutation rates, suggesting that they are in a state of rapid evolution.<sup>6</sup>

Most mycoplasma genomes have a low guanine plus cytosine (G+C) content, within the range of 24–33% G+C. Mycoplasmas are difficult to study by classical genetic tools, both because of their fastidious growth requirements, and as a consequence of the absence of selectable markers. Furthermore, in contrast to other bacteria but similar to mitochondria, *Mycoplasma* use the UGA codon to code for tryptophan instead of the common STOP signal. This means that expression of mycoplasma genes in common bacterial systems is complicated due to the synthesis of truncated proteins.

In this chapter, the designation ureaplasmas will be used where the species has not been determined or where it is irrelevant. Apart from ureaplasmas, *M. hominis*, and *M. genitalium*, *M. fermentans*, *M. penetrans*, *M. primatum*, and *M. spermatophilum* are believed to primarily reside in the urogenital tract. However, as the detection rate of the latter four is generally low, and as their pathogenic potential is not determined, these species will not be discussed in more detail here.

## Epidemiology

### COLONIZATION OF INFANTS AND CHILDREN

Infants may become colonized with genital mycoplasmas during passage through the birth canal; infants who are delivered by caesarean section are colonized less often than those delivered vaginally,<sup>7</sup> but intrauterine transmission also occurs.<sup>8</sup> Ureaplasmas and *M. hominis* may be transmitted to about 40% of babies born to infected mothers<sup>9</sup> and have been isolated from the genitalia or respiratory tract of up to one-third of infant girls. Boys are less frequently colonized and tend to clear the colonization earlier.<sup>7,10</sup> Genital mycoplasmas are rarely recovered from urine or genital-tract specimens from prepubertal boys, and in <10% of prepubertal girls. In sexually abused children, figures of as much as 48% and 34%, respectively, have been recorded.<sup>11</sup> Since *M. genitalium* can be detected in the cervix, vagina, and endometrium, the potential for neonatal infection exists. However, in most populations of pregnant women, the detection rate is well below 5%<sup>12</sup> and only a single case of detection of *M. genitalium* in a neonate has been reported to date.<sup>13</sup>

## COLONIZATION OF ADULTS

In adults, the colonization rate with *M. hominis*, *M. genitalium*, and ureaplasmas increases proportionally with the number of different sexual partners.<sup>14–17</sup> Ureaplasmas can be found in the cervix or vagina of 40–80% of sexually active, asymptomatic women, and *M. hominis* in 20–50%. The colonization rate is somewhat lower in the urethra of healthy males. In women, colonization is strongly linked to bacterial vaginosis (BV); a fact that has led to much confusion in the interpretation of their role in diseases where BV is a risk factor. In contrast to the very frequent detection of ureaplasmas and *M. hominis*, *M. genitalium* is found in only 1–3% of sexually active men and women in population based studies,<sup>16,17</sup> whereas it can be detected in about 5% of asymptomatic sexually transmitted disease (STD)-clinic attendees.<sup>18</sup>

## Clinical Manifestations and Sequelae

Ureaplasmas and *M. hominis* are very frequently isolated from the lower genital tract of healthy individuals. Probably, the organisms only reach the upper tract in a subpopulation of individuals infected in the lower urogenital tract, and disease may only develop in some of the individuals with ascending infection. Consequently, in most cases, they should primarily be considered as commensals when detected in the lower genital tract. However, these mycoplasmas are recognized as common causes of extragenital disease in immunocompromised patients and in newborn infants, particularly preterm infants. In contrast, the link between detection of *M. genitalium* and disease is much stronger.

## Disease in Men

### NONGONOCOCCAL URETHRITIS

*M. genitalium* has been strongly and uniformly associated with nongonococcal urethritis (NGU) in more than 30 studies, and has been detected in the urethra of 15–25% of men with symptomatic NGU compared to about 5–10% of those without this disease.<sup>19</sup> In those studies where the association with nonchlamydial NGU (NCNGU) was evaluated, the association has generally been stronger, suggesting that *M. genitalium* and *C. trachomatis* may act as separate causes of the condition. In several studies, *M. genitalium* has been found in more than one-third of men with NCNGU.<sup>20–24</sup> Among STD clinic populations, approximately 90% of *M. genitalium*-infected men have microscopic evidence of urethritis and almost three-fourths report symptoms.<sup>25–28</sup> Quantitative PCR assays for *M. genitalium* has shown a dose/response relationship between signs and symptoms of urethritis and *M. genitalium* DNA load in urethral and urine specimens, further supporting the causal relationship of *M. genitalium* with urethritis.<sup>29,30</sup> Finally, animal experiments have demonstrated that intraurethral inoculation of male primates with *M. genitalium* results in the development of urethritis, shown most impressively in chimpanzees with shedding of the organism for up to 18 weeks after inoculation and transmission of the organism from infected

to uninfected chimpanzees. Furthermore, an antibody response could be detected in most of the chimpanzees; thus, fulfilling Koch's postulates of causation.<sup>31,32</sup>

Several clinical studies have shown a strong correlation between *M. genitalium* and persistent or recurrent NGU, probably due to the poor microbiologic treatment efficacy of tetracyclines. *M. genitalium* has generally been eradicated from less than 1/3 of the infected patients after treatment with standard doses of tetracyclines.<sup>33–35</sup> *M. genitalium* has been found in as many as 41% of men with persistent or recurrent urethritis after treatment with doxycycline.<sup>36–38</sup> More recently, azithromycin treatment failure after a 1 g single dose was reported among 28% of men with *M. genitalium*-positive NGU and was correlated with macrolide resistance developing during treatment with a single dose in most patients.<sup>39</sup>

In contrast to the consistency of studies associating *M. genitalium* with NGU, the role of the ureaplasmas in this disease has been more controversial. The results of human<sup>40,41</sup> and animal inoculation studies,<sup>42</sup> together with those of controlled antibiotic and serologic investigations, support a causal role for ureaplasmas in NGU, particularly chronic disease,<sup>36,43</sup> although they lag behind *Chlamydia trachomatis* and *M. genitalium* in importance. Obviously, demonstrating ureaplasmas in a man with NGU does not necessarily indicate that this organism is the cause of the disease considering the high colonization rate. Thus, the exact proportion of cases for which ureaplasmas are responsible is difficult to establish. The division of the human ureaplasmas into two species, *U. urealyticum* and *U. parvum*, respectively,<sup>44</sup> led to studies aiming at showing that one of the species was primarily causing disease whereas the other was a commensal.<sup>45–47</sup> *U. parvum* was isolated more often from the control group indicating that this species has a lower pathogenic potential. However, the role of *U. urealyticum* is still uncertain as one study showed an association between this species and NGU<sup>46</sup> whereas another did not.<sup>47</sup> The third study showed an association when crude data was analyzed, whereas only young age was associated with *U. urealyticum* when a logistic regression analysis was applied.<sup>45</sup> Furthermore, in only a few studies has there been control for infection with *C. trachomatis* or *M. genitalium*. Predisposing factors, such as a lack of mucosal immunity in individuals who develop disease, are likely to play a significant role as indicated by a single study where repeated inoculation of a human subject led to a gradual decrease of the inflammatory response.<sup>48</sup> Some patients with hypogammaglobulinemia develop a prolonged urethritis with persistent ureaplasma infection.<sup>49</sup> In such cases, treatment is often complicated by antimicrobial resistance and a combination of different classes of antibiotics is recommended.

There is no evidence supporting a role for *M. hominis* as a cause of urethritis.<sup>27,50</sup>

### PROSTATITIS

A number of studies reported the isolation of ureaplasmas from expressed prostatic secretions obtained after prostatic massage

more often and in greater numbers in men with chronic prostatitis than in controls.<sup>51,52</sup> However, unequivocal evidence for a causal role in acute disease does not exist. *M. genitalium* has been detected by PCR technology in prostatic biopsies from 5 of 135 men and in semen from 2 of 18 men with chronic abacterial inflammatory prostatitis compared to none of 20 controls.<sup>53</sup> However, further studies are needed to confirm these findings. Ureaplasmas have not been found in prostatic biopsies from patients with chronic abacterial prostatitis,<sup>54</sup> and *M. hominis* has not been associated with prostatitis of any kind in most studies.

## EPIDIDYMITIS

Ureaplasmas have been recovered from the urethra and directly from epididymal aspirate fluid, accompanied by a specific antibody response, in a patient with acute nongonococcal, nonchlamydial epididymitis.<sup>55</sup> Clinical experience as well as the detection of *M. genitalium* in a few patients during a treatment trial<sup>56</sup> indicate that *M. genitalium* may be a cause of acute epididymitis. However, further studies are required to establish a causal role.

## Disease in Women

### BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is one of the most common genital infections among women of reproductive age<sup>57</sup> affecting 5–25% of all women. However, its etiology is largely unknown. BV is characterized by a disturbance of normal vaginal flora, with a loss of hydrogen peroxide-producing *Lactobacillus* species and an increase in gram-variable coccobacilli, anaerobic organisms, as well as *M. hominis* and, to a lesser extent, ureaplasmas.<sup>58,59</sup> Both ureaplasmas and *M. hominis* are found in higher numbers in the vagina of women who have BV than in healthy women.<sup>60</sup> However, since the mycoplasmas exist with a variety of other bacteria, also in large numbers, their role in the symptoms and sequelae of BV is not clear. Notably, the mycoplasmas seem to disappear after successful treatment of BV with metronidazole, which has no activity against mollicutes.<sup>61</sup> *M. genitalium* does not seem to be associated etiologically with BV,<sup>59,62</sup> although in some studies it has been detected more frequently in women with BV than in those without.<sup>63</sup>

The strong association between ureaplasmas, *M. hominis*, and BV raises significant problems in determining the roles of these two bacteria in female genital tract infections as BV is a strong predictor of infectious complications in women and as BV has not regularly been controlled for in studies of urogenital mycoplasmas.

### CERVICITIS

One of the major problems in interpreting studies on the association between urogenital mycoplasmas and cervicitis is the lack of a uniform definition of cervicitis. Some studies consider the presence of 10 polymorphonuclear leukocytes (PMNLs) in a cervical smear significant, whereas others demand 30 PMNLs/

hpf to define cervicitis. Also, vaginal leukocytosis (i.e., more PMNLs than epithelial cells in a vaginal wet smear) or the presence of macroscopic cervical mucopus is commonly used and the specificity of these signs has not been thoroughly validated.

In most, but not all studies, *M. genitalium* has been associated with cervicitis. Several studies, however, failed to show significant differences and in general, the association is much weaker than that between *M. genitalium* and male urethritis. In an early study by Uno et al., *M. genitalium* was detected in 8% of women with cervicitis as compared to none of 80 asymptomatic pregnant women.<sup>64</sup> Manhart et al. found *M. genitalium* in 11% of women with cervicitis ( $\geq 30$  PMNLs/hpf) and in 5% of women without cervicitis. In a multivariate logistic regression analysis *M. genitalium* remained strongly associated with cervicitis (OR 3.1; 95% CI 1.5–6.8), supporting an independent role for *M. genitalium* as a cause of cervicitis.<sup>62</sup> In a study from Sweden, *M. genitalium* was significantly associated with cervicitis defined as  $\geq 30$  PMNLs/hpf, since 12% of 85 women with cervicitis were *M. genitalium* PCR positive as compared to 5% of 356 without.<sup>26</sup> In contrast, Casin et al. were unable to demonstrate any correlation between the presence of *M. genitalium* and clinical, demographic, or microbiologic data in women with genital symptoms attending an STD clinic in Paris.<sup>65</sup>

In studies where signs of urethritis have been recorded, female urethritis has been significantly associated with *M. genitalium* infection.<sup>26,66</sup>

The role of ureaplasmas and *M. hominis* in cervicitis has not been studied in great detail. Mucopurulent cervicitis has been associated with isolation of ureaplasmas,<sup>67</sup> although the role of bacterial vaginosis as a confounder was not assessed.

### PID AND SEQUELAE

Pelvic inflammatory disease (PID) is caused by microbes in the vagina and cervix ascending and invading the upper genital tract. *C. trachomatis* and *N. gonorrhoeae*, are the best established etiological agents, but the mixed bacterial flora associated with BV has also been implicated as a cause of this condition,<sup>68</sup> and the role of ureaplasmas and *M. hominis* should be considered in that context. In contrast, *M. genitalium* appear to be independent of BV.

*M. hominis* has been recovered more frequently from vaginal and cervical specimens from women with PID than from healthy women.<sup>69,70</sup> However, since *M. hominis* is very closely associated with BV, and since studies linking *M. hominis* to PID did not include an assessment of BV, the data are difficult to interpret. *M. hominis* has been isolated apparently in pure culture from the fallopian tubes of women with salpingitis diagnosed by laparoscopy, but not from women without lesions.<sup>71</sup> In several studies, a 4-fold rise in antibody titer to *M. hominis* has been found more often among women who had PID than among controls, but no control for BV was reported.<sup>69,72</sup> Damage to fallopian tube epithelium has been studied in organ cultures and it was demonstrated that *M. hominis* multiplied and persisted but caused negligible damage.<sup>73</sup>

Although ureaplasmas have also been isolated occasionally directly from the fallopian tubes of patients with PID,<sup>74,75</sup> they have usually been found in association with other known pathogens and are not thought to play a major role.

*M. genitalium* has been detected in the endometrium of 60% of those positive in the cervix, and its presence in endometrial biopsies has been strongly associated with histological endometritis and with recurrent PID.<sup>76,77</sup> This probably reflects the poor effect of doxycycline used as first-line treatment. Tubal scarring has been indirectly linked with *M. genitalium* infection by a significantly higher proportion of women with tubal factor infertility having antibodies against the bacterium compared to women with infertility from other causes.<sup>78</sup> Although antibodies against *M. genitalium* have been found twice as often in younger women with ectopic pregnancy as compared to pregnant controls in one study, the difference was not statistically different.<sup>79</sup> In a single small study, *M. genitalium* was found by PCR more often in idiopathic infertility than in controls.<sup>80</sup> It would be expected, however, that the effect of PID leading to occluded tubes would be better demonstrated by serology than by PCR technology since the infection may have been present long before infertility became apparent. On the other hand, infertility could also be an effect of endometritis, a condition quite strongly associated with *M. genitalium* infection.

*M. genitalium* has been detected by PCR in a few laparoscopically obtained fallopian tube specimens from women with salpingitis,<sup>81</sup> and causes lower genital tract inflammation in chimpanzees<sup>32</sup> as well as salpingitis in marmosets, grivet monkeys, and baboons.<sup>82</sup> Its ability to attach to spermatozoa may mediate the ascension into the upper genital tract.<sup>83</sup>

In conclusion, there is some evidence that *M. hominis* may be a cause of PID, possibly as part of the BV associated flora but there is very little evidence that ureaplasmas have a similar role. *M. genitalium* is not associated with bacterial vaginosis, but there is increasing evidence that it may play a causal role in cervicitis, endometritis, and PID.

## Urinary Tract Disease

### PYELONEPHRITIS AND UTI

*M. hominis* does not appear to play an important role in acute cystitis.<sup>84</sup> However, ureaplasmas have been associated with symptoms of cystitis and with the acute urethral syndrome in women without significant bacteriuria, and have been isolated from up to 25% of suprapubic aspirates from such women.<sup>85,86</sup> No studies have assessed the importance of *M. genitalium* in these conditions although it has been clearly associated with urethral inflammation.<sup>26,66</sup>

Despite the lack of evidence for *M. hominis* causing acute cystitis, it is thought to be involved in up to 10% of cases of acute pyelonephritis.<sup>87</sup> Antibodies in isolation-positive patients were also demonstrated in a high proportion of cases.<sup>88</sup> There is no evidence suggesting a similar role for ureaplasmas, and *M. genitalium* has not been studied. Surprisingly, no systematic studies have been conducted for more than 30 years despite the apparent importance of the observation and the treatment implications.

### URINARY CALCULI

Infection stones may be caused by urea-hydrolyzing bacteria, including *Proteus* and ureaplasmas. These stones are composed of magnesium ammonium phosphate (struvite) and carbonate-apatite and ureaplasmas have been detected in 12–27% of infection stones,<sup>89,90</sup> occasionally in pure culture, and more often in the urine and stones of patients with infection stones, compared to those with metabolic stones.<sup>91</sup> However, the true impact of ureaplasmas in the development of renal calculi remains to be determined.

## Effects of Genital Mycoplasmas on Pregnancy

### INFERTILITY

Although ureaplasmas and *M. hominis* have been associated with both male-factor and female-factor infertility in some studies, no convincing evidence has been obtained.

### ADVERSE PREGNANCY OUTCOME

Studies based on the detection of ureaplasmas and *M. hominis* from the endometrium or placenta have shown a more consistent association with spontaneous abortion than have studies where the mycoplasmas have been sought only in lower genital tract specimens, but whether the organisms are responsible is unclear. However, the strong link between BV and *M. hominis* in particular should always be borne in mind, since BV has been associated with both preterm labor and stillbirth.<sup>92</sup>

Ureaplasmas have been isolated more frequently from spontaneously aborted fetuses and stillborn or premature infants than from induced abortions or normal full-term infants. Ureaplasmas have been isolated from the lungs and from the brain, heart, and viscera suggesting that it was not just superficial contamination.<sup>93,94</sup> Whether the invasion occurred before or after the fetal death, however, is not clear.

Chorioamnionitis and mycoplasmal infection have been shown to be significantly associated, even when corrected for the duration of membrane rupture.<sup>95–97</sup> Both ureaplasmas and *M. hominis* can invade the amniotic sac before 20 weeks of gestation in the presence of intact fetal membranes and apparently in the absence of other microorganisms.<sup>97</sup> Detection in mid-trimester amniotic fluid has been associated with preterm premature rupture of the membranes with subsequent preterm birth.<sup>98,99</sup> However, not all infected women delivered preterm.

Isolation of ureaplasmas from the placenta is significantly associated with histologic chorioamnionitis and funisitis, stillbirth, and perinatal morbidity and mortality.<sup>100,101</sup>

The isolation of *M. hominis* from amniotic fluid is almost always associated with clinical symptoms (maternal fever, uterine tenderness, foul vaginal discharge). Ureaplasmas, on the other hand, have been known to persist in amniotic fluid for as long as 2 months, in the presence of an intense inflammatory response, sometimes without clinical signs or symptoms of amnionitis.<sup>97</sup>

*M. genitalium* has been associated with preterm birth in a few studies,<sup>102,103</sup> but not in others.<sup>12,104,105</sup> It is usually found at a low prevalence in pregnant women and as such, is probably relatively unimportant during pregnancy.

## NEONATAL INFECTIONS

Ureaplasmas can be isolated from the respiratory tract of neonates. The isolation rate appears to correlate strongly with birth-weight as infants of very low birth-weight (under 1000 g) are infected much more often than full-term infants.<sup>106</sup> A meta-analysis has shown that ureaplasma colonization of the lower respiratory tract of infants <1500 g increases the risk of development of chronic lung disease.<sup>107</sup> *M. hominis* has very rarely been implicated in pneumonia soon after birth, but both *M. hominis* and ureaplasmas have been isolated from the cerebrospinal fluid of neonates with meningitis or brain abscess and should be considered in culture negative neonatal meningitis.<sup>108</sup>

## BLOODSTREAM INFECTION

Ureaplasmas and *M. hominis* can contribute significantly to bloodstream infections in an obstetric and gynecological setting each accounting for almost 10% of positive cultures.<sup>109</sup> When *M. hominis* has been isolated from the blood, an antibody response can be almost uniformly demonstrated.<sup>110,111</sup> While *M. hominis* and ureaplasmas are not highly pathogenic and many patients recover spontaneously, the infections contribute to increased length of hospital stay and costs associated with the investigation of fever postpartum or postoperatively.

It is important to realize that most commercially available blood culture media contain sodium polyanethol sulfonate (SPS), which inhibits the growth of mycoplasmas<sup>112</sup>; consequently, special media should be employed when mycoplasma infection is suspected.

## SEXUALLY ACQUIRED REACTIVE ARTHRITIS

Arthritis occasionally develops concomitantly with or shortly after NGU. This is generally referred to as sexually acquired reactive arthritis (SARA). If the SARA is associated with conjunctivitis and urethritis, the condition is referred to as Reiter syndrome. *M. genitalium* has been detected in the synovial fluid of a patient with SARA<sup>113</sup> and clinical experience has shown that SARA is not uncommon after *M. genitalium*-positive NGU, but no systematic studies have been presented. The evidence for a role of ureaplasmas in SARA is mainly indirect and based on a specific response of synovial mononuclear cells to antigens from ureaplasmas.<sup>114</sup>

## Mycoplasma Infections in Immunodeficient Patients

Patients with antibody deficiencies, such as hypo- or agammaglobulinemia, are particularly susceptible to extragenital mycoplasma infections. *M. hominis* and ureaplasmas have been found in septic arthritis, osteomyelitis, subcutaneous abscesses, and cellulitis.<sup>115</sup> Cystitis and chronic urethritis is common and it is

often very difficult to eradicate the mycoplasmas.<sup>116,117</sup> Prolonged intravenous and combination therapy with increased dosages of antibiotics should be considered to avoid antimicrobial resistance developing due to suboptimal drug concentrations at the infection site, and the gammaglobulin dosage should be increased. In general fluoroquinolones with extended gram-positive spectrum such as moxifloxacin are recommended due to their bactericidal effect and potency against a broad spectrum of mollicutes but always in combination with another antibiotic class such as tetracyclines.

## Diagnosis

*M. hominis* and ureaplasmas are found so commonly in the lower genital tract of healthy men and women that the mere detection of these species should be interpreted cautiously. In contrast, *M. genitalium* is less frequently detected in healthy individuals, and detection should in general lead to treatment. In most situations, swabs from the urethra or cervix/vagina provide a slightly better specimen for mycoplasmal detection than urine specimens. Ureaplasmas and *M. hominis* usually show evidence of growth in special culture media within 1 to 5 days. Primary isolation of *M. genitalium* is difficult and may take 50 days or more, and consequently, PCR is used to detect this species. PCR assays for detection of *M. hominis*, *M. fermentans*, *M. pirum*, *M. penetrans*, and *U. urealyticum/U. parvum* are also available in some laboratories. Mycoplasmas are fastidious and demanding in their requirements for special media. Commercially available media may be useful but are often significantly less sensitive than media produced in mycoplasma-experienced laboratories using quality-controlled ingredients documented to support growth of recent clinical isolates. Without documented proof of adequacy, negative cultures have little meaning.

*M. hominis* grown on solid medium produces colonies of about 200–300 µm diameter, whereas ureaplasma colonies are small (10–70 µm). *M. hominis* may grow on ordinary blood agar where it produces pinpoint colonies after extended incubation. Ureaplasma colonies are too small to be detected on blood agar, but occasionally a scrape from the agar surface will yield ureaplasmas when inoculated into ureaplasma medium. In a few research laboratories only, serological tests have been used to detect antibodies to *M. hominis*, *M. genitalium*, and the ureaplasmas but serodiagnosis cannot be recommended for routine diagnostic purposes.

## Treatment

The genital mycoplasmas have different *in vitro* antimicrobial susceptibilities and resistant strains of all species have been found. Knowledge about the local resistance pattern may often be of value. Furthermore, *in vitro* susceptibility data may not always correlate with clinical experience as exemplified by the apparent *in vitro* susceptibility of most *M. genitalium* strains to tetracyclines in contrast to the lack of eradication in 70–80% of infected patients.<sup>34,35</sup> Before treating *M. hominis* or ureaplasmas, the first consideration is whether to treat or not. The high carriage rate among healthy adults should always be kept in mind.

The main antibiotic classes used for treatment of mycoplasmas are the tetracyclines, the macrolides, quinolones, and clindamycin. Within these classes, significant differences in potency may exist and differences in penetration and accumulation in various tissues should be considered when choosing the antibiotic. Treatment of infections with *M. hominis* can be achieved with tetracyclines, quinolones, and clindamycin, whereas *M. hominis* is intrinsically resistant to macrolides. Ureaplasmas are susceptible to tetracyclines, quinolones, and macrolides, whereas clindamycin is mostly inactive. *In vitro*, clarithromycin is the most potent macrolide, but no large scale clinical trials have been performed to show whether this is a clinically significant difference from other macrolides. In clinical trials, doxycycline appears to be slightly more efficient than clarithromycin in eradicating ureaplasmas, but slightly less clinically efficient and with a higher proportion of gastrointestinal adverse events.<sup>118</sup>

*M. genitalium* is generally susceptible to tetracyclines, macrolides, and quinolones *in vitro*, although tetracyclines are clinically ineffective. Clindamycin is inactive in most strains *in vitro*, but no clinical trials have been performed. Apparently, *M. genitalium* is in most settings highly susceptible to azithromycin.<sup>119</sup> However, recent evidence has suggested that the use of azithromycin 1 g single dose for the treatment of NGU of unknown etiology is strongly associated with high-level macrolide resistance mediated by a single-base mutation in the 23S rRNA gene.<sup>39,120</sup> Thus, the optimal treatment of *M. genitalium* infections may differ according to the local standard therapy for *C. trachomatis* infections and NGU of unknown etiology. Clinical experience suggests that where doxycycline is the drug of choice, azithromycin 500 mg day 1 followed by 250 mg days 2–5 is efficient, whereas in areas where azithromycin 1 g single dose is used for NGU treatment, the extended dosage scheme may fail in 30–90% of the patients. In such treatment failures, moxifloxacin 400 mg od for 7 days appear to be efficient and one of the very few alternatives available.<sup>121</sup>

### Summary

The four mycoplasma species most commonly found in the human urogenital tract are *Mycoplasma genitalium*, *M. hominis*, *Ureaplasma urealyticum*, and *U. parvum*, respectively. Ureaplasmas and *M. hominis* can be found in a large proportion of healthy individuals leading to difficulties in the interpretation of their role as pathogens. *U. urealyticum* appears to be associated with male urethritis when found in large quantities, whereas *U. parvum* has been found more commonly in healthy individuals. *M. hominis* and to a lesser extent the ureaplasmas are strongly associated with bacterial vaginosis making their role in upper genital tract infection in women controversial. In contrast, *M. genitalium* is a well-established cause of non-gonococcal urethritis in both men and women, of cervicitis in women and most likely also of upper genital tract infections in both sexes.

Diagnosis of *M. genitalium* infections rely on nucleic acid amplification tests, as culture is extremely slow and difficult; the preferred treatment is azithromycin in extended dosage as 1 g single dose lead to development of macrolide resistance. Moxifloxacin is currently the only proven alternative in treatment failure after macrolides.

# Sexually Transmitted Anorectal Infections and Enteric Bacterial Infections

Jason C.B. Goh • S. Joseph Wincelhaus

## 47

### Introduction

The gastrointestinal tract represents an important portal and primary site for sexually transmitted infections (STIs). This chapter describes the anorectal and enteric bacterial conditions separately.

### ANORECTAL SEXUALLY TRANSMITTED INFECTIONS

A significant number of STIs can affect the anorectum. Unless a high degree of awareness is maintained, the protean manifestations of these infections in this anatomical site may be confused with other conditions, resulting in misdiagnosis or delayed diagnosis.<sup>1-3</sup> Accurate diagnosis is important not only because these infections carry a considerable morbidity but also because the associated infections in sexual partners, who may remain asymptomatic, will go undetected.

The perianal skin and the anal canal, which extends for 2 cm up to the dentate line where it meets the rectum, are lined by keratinized stratified columnar epithelium. As such, STIs affecting this area share similar appearances and cutaneous symptoms with those affecting the genitalia, such as herpes simplex virus (HSV), syphilis, chancroid, and genital warts. In addition, the anal canal is richly innervated resulting in intense pain, tenesmus, obstructed defecation, and constipation when affected. Anal intercourse or sex toys may result in anal fissure, rectal prolapse, traumatic rectal bleeding, and retained foreign objects or perforation.

Proximal to the dentate line, the anorectum is a capacious reservoir lined by columnar epithelium.

STIs affecting the rectum can produce inflammation of the rectum known as proctitis, which may cause passage of pus or mucus, rectal bleeding (hematochezia), and sensation of incomplete evacuation (tenesmus). The rectum is innervated via the visceral plexus and is therefore not susceptible to painful cutaneous stimuli like the perianal skin. This explains the relatively asymptomatic nature of rectal STIs and how patients may present to their primary care doctors or even gastroenterologists with symptoms, without making a connection with STIs. If the inflammation affects the distal bowel beyond the first 15 cm

(the length of the rectum), it is often termed distal or left-sided colitis, or proctosigmoiditis. The symptoms of a more extensive distal colitis are those of bloody or mucopurulent discharge and even bloody diarrhea. A pan- or total colitis is the term used to describe total or near total inflammation of the colon.

### Inflammatory Conditions

Inflammatory conditions affecting the anorectum, depending on their severity, may or may not be symptomatic. Symptomatic infections commonly present with mucopurulent rectal discharge and/or tenesmus. Three common STIs presenting mainly as inflammatory proctitis are seen in clinical practice: (i) proctitis due to *Neisseria gonorrhoeae*, (ii) proctitis caused by *Chlamydia trachomatis* of the D-K serotypes, and (iii) non-gonococcal and non-chlamydial proctitis.

The first two conditions can be seen in men who have sex with men (MSM), women practicing receptive anal intercourse and in women with genital tract infections due to the two agents. The last condition is almost exclusively diagnosed in MSM presenting with sexually acquired proctitis, negative for not only *N. gonorrhoeae* and *C. trachomatis*, but for HSV as well. In the case of women, proctitis due to *N. gonorrhoeae* and *C. trachomatis* may not necessarily be associated with receptive anal intercourse.

### Rectal Gonorrhoea

The patient may present with rectal discharge and discomfort 5–7 days after exposure, and on proctoscopy the anal canal and rectal mucosa may appear inflamed and friable (Fig. 47.1). The material for culture and Gram stain should be obtained using a swab inserted through the anus or under direct vision on an anoscope. Gram-stained microscopy of rectal material may reveal a large number of polymorphonuclear leukocytes (Fig. 47.2) and the characteristic gram-negative intracellular diplococci (Fig. 47.3). Cultures should confirm this as *N. gonorrhoeae*. Appropriate antibiotic sensitivity tests on the isolates are nowadays mandatory for the proper management of this infection.

**Fig. 47.1:** In gonococcal proctitis, inflamed and friable rectal mucosa is visible on proctoscopic examination. (Reproduced with permission from: Schofield JB, Wincelhaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

**Fig. 47.2:** In non-specific proctitis, gram-stained microscopy of rectal material showing a large number of polymorphonuclear leukocytes. (Reproduced with permission from: Schofield JB, Wincelhaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

**Fig. 47.3:** In gonococcal proctitis, gram-stained microscopy of rectal material showing a large number of polymorphonuclear leukocytes with gram-negative intracellular diplococci. (Reproduced with permission from: Schofield JB, Wincelhaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

DNA detection techniques that are widely used in the evaluation of urogenital STIs are now being used in anorectal STIs. The ligase chain reaction (LCR) has been shown to be 96.5% concordant with culture and is 99.5% sensitive.<sup>45</sup> However, the use of nucleic

acid amplification tests (NAATs) has not been fully validated in anorectal STIs and is not yet recommended by IUSTI.<sup>6</sup>

It is noteworthy that male sexual contacts of index cases of rectal gonorrhea are more often asymptomatic and serve as the main reservoir for infection.<sup>5,7</sup> Recreational drug use, engagement in anonymous sex, multiple sexual partners, and HIV positivity are also risk factors for rectal gonorrhea and screening for *N. gonorrhoeae* in these at-risk groups who are sexually active is recommended.<sup>8</sup>

Treatment for rectal gonorrhea should follow the standard treatment for uncomplicated urogenital gonorrhea plus concurrent treatment for chlamydia.

### Rectal Chlamydia

Chlamydia genotypes A-K (genotype trachomatis) can be diagnosed by NAAT testing of a rectal swab if facilities are available.<sup>9,10</sup> Otherwise, empirical treatment is recommended with doxycycline 100 mg twice daily orally for 7 days.

### Lymphogranuloma Venereum (LGV)

LGV is an STI due to the LGV serovars of *C. trachomatis* - L1, L2, and L3. It is an infection mainly of the lymphatic system. In the genitoanorectal stage of the infection, which is mostly seen in women and MSM, there is a severe proctitis where the rectal mucosa may appear congested, hyperemic, friable, and studded with multiple superficial ulcers.<sup>7</sup> These changes may extend to the distal colon. The patient may be wrongly treated by gastroenterologists for proctitis of the ulcerative colitis or Crohn disease phenotypes as the relevant sexual history may not be actively sought or volunteered. LGV is described in detail in Chapter 41.

### Non-specific Proctitis

Apart from the specific causes of proctitis mentioned above, MSM practising receptive anal intercourse whose partners develop non-gonococcal and non-chlamydial urethritis very often present with a non-specific proctitis (NSP). Where *C. trachomatis* or *N. gonorrhoeae* cannot be isolated or identified, a diagnosis of NSP is usually made on the findings on microscopy of a gram stained rectal smear showing a large number of polymorphonuclear leukocytes. Occasionally, anorectal HSV infection may present only with inflammatory changes. Traditionally, therefore, infection with this virus is excluded as well before the diagnosis of NSP is established. As in non-specific urethritis, treatment with azithromycin, tetracyclines or erythromycin is often effective.

### Ulcerative Conditions

The common STIs presenting with ulcerative lesions in the anorectum are:

- HSV infection,
- Syphilis,
- Chancroid,
- Donovanosis,
- Cytomegalovirus (CMV) infection,

### Herpes Simplex Virus

Herpes simplex virus (HSV) infection is the single great masquerader in the anorectal region both in men and women.<sup>1,2</sup> Acute HSV infection can affect the perianal skin, anal canal, and/or the rectum. It can be asymptomatic but usually presents with severe anal pain and may take the form of an ulcerated or friable proctitis or proctocolitis.<sup>11,12</sup> Ulcers may be single or multiple. Solitary ulcers on the anal verge can easily be mistaken for anal fissures. These ulcers may extend on to the perianal skin (Fig. 47.4) and the resulting pain may make clinical assessment difficult. Other associated clinical features to look for include constitutional symptoms of fever and malaise, tender inguinal adenopathy, constipation, and urinary retention.<sup>13</sup> Urinary retention and constipation may occur as painful spasms associated with anorectal HSV and may be a consequence of sacral nerve root involvement.

HSV-2 is responsible for over 90% of anorectal HSV infections and is a common cause of proctitis in MSM practicing receptive anal sex.<sup>14</sup> Yet, HSV-1 may be responsible for a greater or lesser percentage of these infections in various parts of the world depending on the local frequency of oroanal sexual practices. In fact, where there are relatively large gay male populations such as along the eastern seaboard cities of Australia, HSV-1 seems to be responsible for 20–30% of primary anal herpes infections. Condoms seem mostly to be used for penetrative penoanal sex, but dams are hardly ever used for oroanal sex, which may explain this HSV-1 epidemiology.

Following acute infection, the large enveloped DNA virus may remain dormant before reactivating causing asymptomatic infections or relapsing ulcers. Recurrent anal herpes may be seen in up to 40% of patients infected with HSV in the anorectum.<sup>15</sup> However, chronic persistent anal herpes is usually associated with HIV<sup>16</sup> when patients may present with fissures and ulcers

**Fig. 47.4:** Perianal fissures and ulcers of herpes simplex virus infection. (Reproduced with permission from: Schofield JB, Wincelous SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

**Fig.47.5:** A histological section of perianal herpes showing spongiotic, ulcerated mucosa, and intranuclear inclusions. (Reproduced with permission from: Schofield JB, Wincelous SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

affecting the anal margin and anal canal, sometimes extending into the rectum. Suspecting the diagnosis will give a clue to the underlying immunodeficiency.<sup>2</sup> Relapsing anal herpes may masquerade as recurrent or chronic anal fissures and may confuse an unwary clinician. Crohn disease and solitary rectal ulcer syndrome, especially if the ulcer is surrounded by erythema, may also be confused with anorectal herpes.

Viral cultures and typing from swabs are diagnostic but testing for HSV DNA by PCR is highly sensitive and should be used routinely.<sup>6,15</sup> Ulcer biopsies are taken occasionally, but histopathological features in HSV infection can be quite subtle comprising intranuclear inclusion bodies within epithelial cells at the edge of the ulcer.<sup>17</sup> They show central pallor of the nucleus with peripherally displaced nuclear chromatin (Fig. 47.5).

Although an acute attack is usually self-limiting, treatment with acyclovir or other antivirals as per genital HSV is recommended. Testing for HIV should be offered in all cases.

### Syphilis

Anorectal infection caused by *Treponema pallidum* results in a primary chancre appearing either on the anal verge or in the anal/rectal canal 2–6 weeks following exposure.<sup>18</sup> This is usually seen in MSM infected during receptive anal intercourse.<sup>19</sup> The incidence of syphilis has been rising in recent years and outbreaks have been described in the United Kingdom and elsewhere, primarily among MSM.<sup>20–23</sup> In parts of the USA, the incidence of early syphilis among MSM has doubled between 2003 and 2005.<sup>22</sup>

Ulcers on the anal verge have a firm raised edge and may or may not be painful. Painless lesions could easily be missed or dismissed as traumatic. The primary chancre may not always be associated with inguinal adenopathy in lesions confined entirely to the anorectal area. However, inguinal adenopathy, if present, serves as a useful marker for the infection especially if they are rubbery and painless. Proctoscopic evaluation is necessary to exclude ulcers involving the anal canal or the rectum. Within the anal canal and the distal rectum reported findings include erythema, mucosal ulcers, polyps, and even lobulated masses.<sup>24–26</sup> The associated enlargement of regional lymph nodes with minimal

mucosal non-ulcerative changes can lead to misdiagnosis.<sup>25</sup>

Nevertheless, early anorectal syphilis is far more likely to be diagnosed at the secondary stage than in the primary stage. Patients who reach the secondary stage of infectious syphilis with the ulcers still persisting may also present with fever, maculopapular skin eruptions, and generalized lymphadenopathy. Perianal condylomata lata, the moist and highly infectious soft polypoid growths associated with secondary syphilis, may sometimes be seen (Fig. 47.6). This is usually pruritic and exudative. Within the anorectal canal itself the diverse mucosal lesions described above could still be seen during the secondary stage of the infection.

Where ulcers are accessible, dark field microscopy of serous exudate from the ulcers will show the Treponemes with their characteristic spiral morphology. It has to be interpreted in the context of non-pathogenic spirochetes being an “innocent bystander” within the gastrointestinal tract in some individuals. Histology often reveals a characteristic intense plasma cell infiltrate in early syphilis as seen in chancres and syphilitic gummas. Silver stain and immunofluorescent stain can be useful for detection of the Treponema in the biopsy sample. Where available, multiplex NAAT for *T. pallidum* DNA from the biopsy sample or exudates material can be used.<sup>27</sup>

Direct fluorescent antibody test for *T. pallidum* can be of use where dark field microscopy is not available or in situations where it is not possible to obtain uncontaminated clear serous exudates from the lesions. Serology (VDRL, RPR), syphilis enzyme immunoassay (EIA), and FTA-ABS testing in the very early stages may be negative and may have to be repeated serially. IgG antibody EIA will also be supportive. These sensitive tests could

**Fig. 47.6:** Moist, polypoid lesions of perianal condylomata lata. (Reproduced with permission from: Schofield JB, Wineslaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

be particularly valuable in the serological diagnosis of anorectal syphilis in HIV-infected persons. The IUSTI recommend HIV testing in all patients with syphilis.<sup>6</sup> See Chapter 36 for treatment.

### Intestinal Spirochetosis

While intestinal spirochetes are a causative agent of diarrhea in animals, their role in the human gut is not at all well-defined. While this does not cause anorectal ulcers, it is described here alongside rectal syphilis. Although a syndrome of diarrhea and rectal bleeding has been ascribed to intestinal spirochetes of the genus *Brachyspira* in a part of Italy,<sup>28</sup> many other studies do not support a causal relationship.<sup>29–31</sup> Intestinal spirochetes have been diagnosed in 36–39% of asymptomatic MSM but its prevalence in heterosexual men has not been specifically studied.<sup>32,33</sup>

Intestinal spirochetes are readily identified on hematoxylin and eosin stain.<sup>30,31</sup> Current opinion is that intestinal spirochetes do not cause disease and they are an incidental finding even in patients with symptoms. In exceptional cases where other causes of diarrhea have been excluded or unsuccessfully treated, oral Metronidazole 400 mg three times a day for 10 days may eliminate the spirochetes and relieve symptoms. Treatment for asymptomatic intestinal spirochetosis cannot be recommended.

### Chancroid

Chancroid is caused by the gram-negative bacillus *Haemophilus ducreyi* and is a common cause of genital ulcer in the developing countries of Africa, Asia, and South America, with the highest prevalence reported from southern, central, and eastern Africa.<sup>34</sup> Its link with heterosexual HIV transmission is well-established.<sup>35,36</sup>

Anal infection occurs mostly in women and MSM, and the resulting non-indurated, often-painful ulcers can be destructive. Although the infection can sometimes be asymptomatic in women, tenesmus and rectal bleeding may be the presenting symptoms. Initially, the ulcers tend to be discrete with irregular, undermined edges and greyish yellow base. The ulcers soon coalesce destroying the soft tissues in and around the anus. The suppurating inguinal lymphadenopathy seen with genital lesions may not be seen if the primary infection affects only the anal canal. The differential diagnosis of such anorectal ulcers remains HSV and syphilis depending on the sociogeographical context. *H. ducreyi* infection of the rectum has not been well-documented probably because of the lack of awareness amongst clinicians and the paucity of reliable diagnostic tests available for the condition.

Available diagnostic tests vary depending on the setting in which the infection is suspected. Direct Gram-stained microscopy from scrapings of the ulcers showing the typical “schools of fish” appearance of the gram-negative bacilli is no longer accepted as a reliable method of diagnosis. Different selective enriched culture media are now available for growing the fastidious *H. ducreyi* as well as sensitive PCR assays. This is described further in Chapter 36.

### Donovanosis

Donovanosis or granuloma inguinale is caused by the gram-negative bacillus *Klebsiella granulomatis*. Endemic foci are found in Papua New Guinea, Southeast India, South Africa, Zimbabwe, West Indies, Brazil, northern and central Australia, Vietnam, and Japan. A male preponderance has been noted in most reported series.<sup>37</sup> Although genital and inguinal regions are the common sites of infection, primary perianal infections have been reported.<sup>38,39</sup> After a variable incubation period, the primary site of infection is marked by a papule or nodule, which soon breaks down to the typical red, raw, painless ulcer. The condition is marked by great chronicity and is accompanied by feelings of shame due to the highly offensive smell associated with the larger lesions.<sup>37,40</sup> Late presentation with advanced disease is extremely common due to the stigma associated with this disease in the affected communities.

Primary perianal infection, mostly seen in MSM (Fig. 47.7), may extend to the anal canal and cause rectal bleeding. Chronic lesions may lead to rectovaginal fistulae, or fistulae connecting the rectum to other pelvic organs. Distinguishing chronic lesions in the rectum from malignancies or fistulizing Crohn disease of the perineum may be clinically very difficult.<sup>37</sup> The ulcers spread by soft tissue destruction and the accompanying sclerosis can result in stenosis of the anal canal.

Examination of tissue specimens from the ulcer remains the mainstay of diagnosis of donovanosis. Various staining techniques have been reported to stain cellular material for the presence of Donovan bodies.<sup>37,41</sup> These include, Giemsa or modified Giemsa stain, Leishman stain, and Wright stain. Silver impregnated stains such as Warthin–Starry stain can also be used to stain biopsy tissue. The Donovan bodies are seen as bipolar dense encapsulated organisms stuffed within macrophages. Although culture, PCR

**Fig.47.7:** Red, raw, granulomatous ulcers of donovanosis in perianal region. (Reproduced with permission from: Schofield JB, Wineslaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

methods, and serological tests for the diagnosis of donovanosis have been described; these have not come into general use yet. For treatment refer to Chapter 43.

### Cytomegalovirus Infection

Symptomatic cytomegalovirus (CMV) infection of the rectum or colon is often seen in the context of existing inflammatory bowel disease or immunosuppressed individuals, particularly post-transplantation patients taking antirejection therapy, but is also being increasingly seen in apparently immunocompetent individuals.<sup>42,43</sup> It can also be sexually transmitted in both immunocompetent and immunocompromised hosts. In patients with advanced AIDS, typically those with CD4<sup>+</sup> count of less than 100/ $\mu$ L<sup>3</sup>, CMV can be a causative agent of ulcerative esophagitis, gastritis, proctitis, and proctocolitis.<sup>44,45</sup> Infection is more often due to reactivation of a latent infection but can be primarily acquired.

CMV esophagitis may coexist with candidiasis and present with odynophagia and heartburn. Diarrhea may be watery or bloody depending on the degree of ulceration and extent of colonic involvement. CMV colitis is often associated with a systemic syndrome of fever, loss of appetite, malaise, abdominal pain, and diarrhea. The fulminant form of colitis may lead to toxic dilatation and even perforation.<sup>42,46</sup>

Sigmoidoscopic appearance is similar to that of a confluent colitis but ulceration may be more prominent. Stool cultures are negative for conventional viral and bacterial pathogens. Taking random biopsies are essential for diagnosis. The pathologist needs to be alerted to look out for features of CMV including giant cells with basophilic intranuclear and intracytoplasmic viral inclusion bodies (Fig. 47.8). Specific immunostaining for CMV can be performed on the biopsy samples, and viral cultures and PCR can be performed where available.

In patients with systemic illness, blood and urine may test positive for CMV PCR. Most patients with CMV colitis tend to secrete CMV in the urine. Estimating IgG antibodies against CMV in the serum may not be helpful because of the wide prevalence of the latent infection in the at-risk population. IgM response to reactivation of the disease may not be forthcoming

**Fig.47.8:** Giant cell of CMV infection in a histological section. (Reproduced with permission from: Schofield JB, Wineslaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

in the immunocompromised patient. Measurement of CMV viral load in the serum may be helpful, as the viral load tends to be high during active infection or reactivation.<sup>42,47,48</sup> In patients with confirmed CMV colitis, HIV testing should be considered.

Treatment with Ganciclovir is often effective, with foscarnet and cidofovir as second-line back-up. Relapses can occur and may require some form of maintenance prophylactic therapy until immune function can be restored. The fulminant form resulting in toxic dilatation and intestinal perforation may require colectomy as with patients with inflammatory bowel disease.

### Idiopathic Ulceration in HIV Infection

As in any part of the gastrointestinal tract, anorectal ulceration without apparent cause is common in HIV infected individuals. They can be extremely painful and occasionally cause destruction of the anal sphincter complex. It has been suggested that the HIV infection itself may be directly responsible for these so called “idiopathic” ulcers.<sup>49</sup> However, this diagnosis can only be made after excluding all other causes of anorectal ulcerations in this patient group. Treatment options include topical (intralesional steroid), systemic (thalidomide, prednisolone), and surgical (excision biopsy).<sup>50</sup> They may also resolve with HAART.

## Tumors

### Human Papillomavirus Infection

STIs due to the genital types of human papillomavirus (HPV) infection are becoming increasingly common. The infection may involve the anus and the anal canal but never above the dentate line. These cauliflower-like lesions should be distinguished from squamous cell cancer of the anus and condylomata lata of secondary syphilis.

While it usually affects MSM practicing receptive anal intercourse (Fig. 47.9),<sup>51</sup> it can also be seen in some heterosexual men and women who have never had anal sex.<sup>52</sup> HPV types 6 and 11, which are not linked to anal cancer, cause the majority of anal warts. On the other hand, infection with the oncogenic HPV types 16, 18, 31, 35, 45, and other “high-risk” serotypes, if persistent can lead to anal intraepithelial neoplasia and progress to squamous cell carcinoma of the anus and the anal canal.<sup>53</sup>

Alarming, a community-based study in Sydney using a combination of Digene Hybrid Capture 2 and the Roche linear array assays found almost universal anal HPV infection in the MSM community they sampled.<sup>54</sup> HIV positive men are more likely to be infected with diverse and multiple HPV genotypes than HIV negative men.<sup>54</sup> HPV infection presenting as warts is the most common perianal condition in HIV infected patients in whom the warts tend to be more exophytic and numerous compared to their immunocompetent counterparts.<sup>55</sup> This may in part be due to the reduced immune surveillance but may also be due to infection with multiple and high-risk serotypes.<sup>54–57</sup>

Dysplasia has been reported in 10% of anal warts seen in HIV infected patients.<sup>58</sup> As this is not always associated with obvious warty change seen by naked eye examination, cytological

**Fig. 47.9:** Perianal human papillomavirus infection. (Reproduced with permission from: Schofield JB, Wincelhaus SJ. Anorectal manifestations of sexually transmitted infections. *Colorect Dis* 2001;3:74–81).

screening or biopsy may be necessary for confirmation. Although squamous cell carcinoma of the anorectum triggered by HPV may affect non-HIV infected patients, an increased surveillance is important in the presence of HIV/HPV co-infection although the best screening modality and its efficacy remain unclear.<sup>59</sup> HAART therapy may not reduce the risk of progression to anal intraepithelial neoplasia. Currently available HPV vaccines can potentially prevent the majority of squamous cell carcinoma of the anus but clearly they have to be given before the onset of sexual activity.<sup>60</sup>

The wide variety of treatment for HPV reflects their relative lack of efficacy. Anal HPV can be treated with topical podophyllin but this can potentially result in anal stenosis with long-term use. Cryotherapy is effective but large anal warts in HIV positive individuals may be recalcitrant to treatment. Laser therapy and even surgical excision may be used in these refractory cases. Other treatments such as polyphenon, imidazoquinoline derivatives, and more novel techniques such as Argon plasma photocoagulation and ultrasound-driven Harmonic scalpel have all been advocated with variable outcome. A recent study from London revealed a 63% cure rate, defined as 12-month disease-free state for anal intraepithelial neoplasia using laser ablative treatment.<sup>61</sup>

### Kaposi Sarcoma

Tumors associated with HIV that can be found in the anorectum or elsewhere in the gastrointestinal tract include Kaposi sarcoma (KS) and lymphoma.<sup>62</sup> After the skin, the GI tract is the most common site for KS. AIDS-associated KS affects MSM more commonly than the other groups. There is compelling evidence that the human herpes virus-8 (HHV-8), the etiological agent of KS, may also be sexually transmitted—at least in MSM.<sup>63–65</sup>

In the anorectum, the condition may manifest as a nodule or merely as a discolored patch or plaque. The development of KS in patients with HIV and HHV-8 co-infection may correlate with the degree of immunosuppression seen in these patients. The further advanced the immunosuppression, the more likely it is for HHV-8 to reactivate resulting in KS. This is further borne out by the fact that KS-associated lesions generally regress with the initiation of highly active antiretroviral treatment against HIV.<sup>66</sup> Biopsy and histological examination of suspected lesions remain the commonest method of diagnosing KS. In typical cases, the “sarcoma” is represented by vascular channels with extravasated red blood cells surrounded by spindle-shaped tumor cells. Early lesions, however, may be difficult to diagnose histologically and may not show anything more than a “granulation tissue-like” appearance.<sup>62</sup>

### SEXUALLY TRANSMITTED ENTERIC BACTERIAL PATHOGENS

The principal bacterial pathogens that can be sexually transmitted and cause enteritis (profuse watery diarrhea) and/or colitis include *Shigella*, *Salmonella*, and *Campylobacter*. They are more prevalent in MSM and patients with AIDS than other groups.

Diarrhea is a common symptom in HIV infection. It can be a significant presenting symptom of HIV infection especially in the developing world. The prevalence of persistent and chronic diarrhea has been estimated to be between 17% and 95% for developed and the developing worlds, respectively.<sup>67</sup> Causes of diarrhea include primary HIV infection itself, HAART (especially the protease inhibitors), lymphoma, common pathogens causing gastroenteritis (viral, *Campylobacter*, *Salmonella*, and *Shigella*), and opportunistic infections (viral, bacterial, protozoal, and fungal).

The specific bacterial enteric pathogens that are sexually transmitted are considered below.

### Shigella

*Shigella* comprises a group of gram-negative enteric bacteria that includes four major subgroups—*S. dysenteriae* (group A), *S. flexneri* (group B), *S. boydii* (group C), and *S. sonnei* (group D). *S. dysenteriae*, also known as the shiga bacillus, produces the most severe form of dysentery; while *S. sonnei* produces the mildest disease. In tropical countries, the most common organism is *S. flexneri*, while in United States, most of the bacillary dysentery is caused by *S. sonnei*.

Humans serve as the only reservoir and natural host for *Shigella*. As few as 10 *Shigella* organisms can cause overt clinical illness in volunteers. Most of the transmission is person-to-person and is facilitated by close human contact. The low inoculum of *Shigella* required for transmission and the ability of *Shigella* to survive in acidic conditions during transit through the stomach leads to easy spread of *Shigella* where crowding, poor sanitation, and poor personal hygiene co-exist.

Outbreaks of Shigellosis have been described among communities of MSM in the developed world.<sup>68–70</sup> A case-control study in San Francisco, US, identified risk factors for Shigellosis among men: MSM (Odd ratio 8.24), HIV (OR 8.17), direct oral-anal contact (OR 7.5), and foreign travel (OR 20).<sup>71</sup> This contrasted with women in whom the only identifiable risk factor was foreign travel (OR 21). In a questionnaire study from Berlin, most men had direct or indirect oral-anal sexual contact in the week before they fell ill with Shigellosis.<sup>70</sup>

The pathogenesis of *Shigella* infection depends primarily on a large plasmid that encodes factors permitting the bacteria to enter cells, grow freely in the cytoplasm, and spread directly to adjacent cells.<sup>72</sup>

*Shigella* is able to invade both the colonic enterocytes (epithelial cells) and the specialized M cells that overlie lymphoid follicles. *Shigella* invades epithelial cells from the basolateral surface by use of a type III secretion apparatus, which confers its virulence factor. Two proteins secreted via the type III apparatus, Ipa A and Ipa C, are inserted into host cell membranes and appear to mediate cell entry directly.<sup>73,74</sup> The bacteria then spread to adjacent cells and to macrophages which they kill by inducing apoptosis while releasing IL-1.<sup>75</sup> Although enterotoxins are expressed, their contribution to the disease process is unclear.

Clinically, *Shigella* dysentery is characterized by high fever, toxemia, abdominal cramps, tenesmus, frequent bloody mucoid stools, and vomiting. The spectrum of *Shigella* includes asymptomatic infection to severe dysentery.

The incubation period is 1–4 days. The progression of disease occurs through distinct phases in shigellosis. At the onset of clinical illness, there is toxemia and high fever, followed hours later by watery diarrhea. Later, it leads to passage of scanty stools of blood and mucus. Severe dysentery is most likely to occur in infection with *S. dysenteriae* type I, less commonly with *S. flexneri*, and is least likely in *S. sonnei* infection. Colonoscopy shows hemorrhagic mucosa with mucus discharge, and focal ulcerations and sometimes an exudate. With extensive colonic involvement, protein-losing enteropathy, toxic megacolon and even perforation can occur. Hemolytic uremic syndrome, leukemoid reactions, and severe hypoproteinemia are recognized complications of *Shigella* dysentery. Rarely, Reiter syndrome follows shigellosis, particularly that due to *S. flexneri* serotypes.

Culture of a fresh stool is optimal. Stool microscopy often shows a great abundance of neutrophilic fecal leukocytes. Measurement of serum antibodies to the O antigen of the specific *Shigella* serotype by ELISA is useful in investigation of outbreaks.

In general, antimicrobial therapy is not indicated for the treatment of *Shigella*, except in those with bloody diarrhea, AIDS or sickle cell disease.<sup>6</sup> However, antibiotic treatment in cases of symptomatic positive stool cultures has been advocated for public health reasons.

It has been shown that appropriate antibiotics significantly decrease the duration of fever, diarrheal illness, and excretion of the pathogen.<sup>76</sup> Resistance to sulfonamides, streptomycin, chloramphenicol, and tetracycline is almost universal and many

*Shigella* are now resistant to ampicillin and trimethoprim-sulfamethoxazole. Where indicated, the drug of choice is ciprofloxacin or nalidixic acid. No antibiotic treatment is recommended for the convalescent carrier stage. Patients with AIDS who develop chronic carriage may require prolonged treatment with a quinolone. Rifaximin is currently being evaluated as prophylactic medication for travelers to hyperendemic regions. For food handlers with Shigellosis, three consecutive negative stool samples taken not less than 24 hours apart, and at least 2 days after cessation of antibiotic therapy should be obtained before they are allowed to return to work.<sup>6</sup>

## Salmonella

There are more than 2000 serotypes of *Salmonella*. Of these, the non-typhoidal *Salmonella* are important causes of infective gastroenteritis and are discussed below in the context of potential oral-fecal sexual transmission and their significance in patients with AIDS. Typhoid fever is an acute systemic illness caused by infection with *Salmonella typhi*. Sexual transmission is uncommon but has been reported anecdotally.<sup>77</sup> Typhoid fever is not discussed here.

### Non-typhoidal Salmonellosis

Common serotypes of non-typhoidal *Salmonella* include *S. typhimurium*, *S. heidelberg*, *S. enteritidis*, *S. newport*, and *S. badar*. Poultry has the highest incidence of *Salmonella* carriage, particularly hens, chickens, and ducks.

Clinical syndromes seen with *Salmonella* are: (i) gastroenteritis, (ii) bacteremia, (iii) localized infection of bones, joints, gallbladder, and meninges. The most common syndrome is gastroenteritis. The usual incubation period is 6–48 hours. Initially, nausea and vomiting are followed by abdominal cramps and diarrhea. The diarrhea is accompanied by fever and bloody stools in 50% of the cases. Occasionally, the patient may develop toxic megacolon and perforation. The course of disease ranges from 1 to 3 weeks.

Sexual transmission of *Salmonella* is uncommon and anecdotal. There is an estimated 20-fold increase in incidence of *Salmonella* infection in patients with AIDS.<sup>78</sup> Patients are more likely to suffer from a more severe clinical illness, bacteremia, and are more likely to have relapses.<sup>79,80</sup> *S. typhimurium* and *S. enteritidis* are responsible for most cases in these patients, and *Salmonella* bacteremia is an AIDS-defining illness. Dysregulation of the proinflammatory cytokine response, including IL-12, by macrophages during *Salmonella* infection in patients with HIV has been implicated as a mechanism for severe clinical disease and bacterial persistence in these patients.<sup>79,81</sup>

Stool culture often yields the diagnosis. Antimicrobial therapy is not advocated for most cases of *Salmonella* gastroenteritis. Treatment does not alter the rate of clinical recovery and antibiotic therapy has been thought to increase the incidence and duration of intestinal carriage of these organisms. Nevertheless, antibiotic treatment is advisable in certain clinical scenarios including severe *Salmonella* colitis or *Salmonella* gastroenteritis in patients with

AIDS, lymphoproliferative disease or sickle cell disease. In acute bacteremia in patients with AIDS, a 2-week course of ciprofloxacin 750 mg twice a day is first-line treatment although this may need to be modified according to the bacterial antibiotic sensitivity pattern. Recurrence of *Salmonella* bacteremia can be as high as 45% in patients with AIDS. Long-term suppressive treatment with ciprofloxacin 500 mg twice a day may be necessary.

## Campylobacter

*Campylobacter jejuni* is one of the most common causes of acute infective gastroenteritis in the world.

Transmission occurs following ingestion of incompletely cooked chicken or other meats and non-pasteurized milk. Person-to-person transmission can also occur in close household contacts and preschool children. Sexual transmission is via the oral-fecal route especially among MSM.<sup>82–85</sup> In a study performed in Baltimore, *Campylobacter* species were isolated from 4%, 20%, and 9% of MSM who were asymptomatic, who had symptomatic diarrhea and who had AIDS, respectively.<sup>86</sup>

*Campylobacter* enteritis produces a syndrome of fever, diarrhea, and abdominal pain. The disease is usually self-limiting and lasts for 1–7 days. Severe bloody diarrhea may mimic acute inflammatory bowel disease and may even be complicated by a fulminant colitis, pseudomembranous colitis, toxic megacolon, and pancreatitis. It is a known cause of post-infective Guillain-Barre syndrome, reactive arthritis, and myopericarditis.

Diagnosis is often obtained by positive stool cultures.

Use of antibiotics is controversial. In patients with bloody diarrhea, fever or worsening symptoms, treatment with erythromycin (500 mg four times a day for 7 days), azithromycin (500 mg daily for 3 days), or ciprofloxacin (250 mg twice daily for 7 days) is recommended. Strains of ciprofloxacin-resistant *Campylobacter* have however emerged worldwide.<sup>86,87</sup>

## Vulvovaginal Candidiasis

### INTRODUCTION

Vulvovaginal candidiasis (VVC) is the most common cause of vaginitis in the tropics and second only to bacterial vaginosis (BV) in the developed nations. About 70–75% of women will have at least one lifetime episode, with 40–50% suffering a recurrence.<sup>1</sup> In 20%, *Candida* may colonize the vagina without producing any symptoms.<sup>2</sup> Overall, 85–90% of candidal vaginitis is caused by *Candida albicans*.<sup>3</sup> Other species in order of incidence include *Candida glabrata*, *Candida tropicalis*, *Candida parapsilosis*, *Candida krusei*, and *Candida guilliermondii*.<sup>4</sup>

VVC includes primary infection, which may be sporadic and is often considered idiopathic, although there is some evidence that sexual intercourse may be a precipitating factor in many cases. VVC may be secondary to other predisposing causes, such as pregnancy, antibiotic usage, diabetes mellitus, and estrogen therapy.

Recurrent vulvovaginal candidiasis (RVVC) occurs in about 5% women.<sup>3</sup> This may be associated with immunosuppression, diabetes mellitus, and may be caused by non-*C. albicans* species. The latter patients may require more complex investigations including full identification and sensitivities.

VVC and RVVC are increasing in incidence and cost. A study in the US showed that in 1995, these conditions cost US \$1.8 billion and it is predicted that by the year 2014, this will rise to US \$3.1 billion. This study also estimated that wrong self-diagnosis may occur in up to 50% of women.<sup>5</sup> There is a concern about the use of over-the-counter and alternative medicines, which may hide or delay the diagnosis of other more serious underlying conditions.<sup>6</sup> There have been interesting developments in the understanding and management of mucocutaneous candidiasis,<sup>7</sup> and also its association with thymoma<sup>8</sup> and the autoimmune polyendocrine syndromes.<sup>9</sup> However, many of these developments are out of the scope of this chapter.

Centers for Disease Control and Prevention (CDC) classification of VVC is shown in Table 48.1.<sup>10</sup>

**Table 48.1:** Classification of Vulvovaginal Candidiasis (VVC)<sup>10</sup>

Uncomplicated
<ul style="list-style-type: none"> <li>• Sporadic or infrequent VVC</li> <li>• Mild-to-moderate VVC</li> <li>• Likely to be <i>C. albicans</i></li> <li>• Non-immunocompromised women</li> </ul>
Complicated
<ul style="list-style-type: none"> <li>• Recurrent VVC</li> <li>• Severe VVC</li> <li>• Non-<i>C. albicans</i> candidiasis</li> <li>• VVC in women with uncontrolled diabetes, debilitation, or immunosuppression, or those who are pregnant</li> </ul>

### HISTORY

Vaginal candidiasis was first described in 1849 and the pathogen was named *Oidium albicans* in 1853.<sup>11</sup> The name was derived from the word *Candida* describing the white robe (toga) worn by Roman Senators and this name was adopted internationally in 1954.<sup>12</sup> Candidal balanitis was first reported in 1920.<sup>13</sup> Over the years with the increasing use of invasive procedures and broad-spectrum antibiotics in medical management, systemic candidiasis has become a major problem in hospitals. It has become important in immunosuppressed patients such as those infected by human immunodeficiency virus (HIV)<sup>14</sup> and in those suffering from neutropenia, e.g., post-bone marrow or solid organ transplantation. Genitourinary Medicine Clinics in the UK have shown an increase in genital candidiasis from 118/100,000 patients in 1975 to 200/100,000 in 1984.<sup>15</sup> In the Western world, it may also be related to the use of tight clothing (including G strings),<sup>16</sup> the increased use of colored and perfumed agents in the genital region, and procedures such as shaving and waxing.

### EPIDEMIOLOGY

*Candida* species are found in humans, animals, and many foodstuffs particularly fruit juices (probably packaging contamination). In humans, *Candida* species are found in the oropharynx and the

rest of the gastrointestinal tract and from there they colonize to the vulvovaginal area. As VVC and RVVC are not reported as sexually transmitted infections, there are limited epidemiological data. Many patients self-treat and present to practitioners only when there is no response to usual household remedies.

VVC is not common in premenstrual girls. It peaks in incidence at 20–40 years of age, and is found in postmenopausal women who are on estrogen supplements or may have underlying pathology.

About 20% of asymptomatic healthy women of childbearing age group carry the infection but this can range between 10% and 50%. About 50% of college women by the age of 25 will have had at least one physician-diagnosed episode of VVC.<sup>1</sup> There has been little research into behavioral factors associated with VVC. However, there is confirmed transmission by vaginal sexual intercourse and other forms of sexual activity including orogenital contact. Eight hundred women attending two sexual health clinics in London for lesbian and bisexual women completed a questionnaire and 88% had a full sexual health check. VVC was associated with more sexual partners and the authors suggest that *Candida* could be sexually transmitted among women.<sup>17</sup> VVC is more common in pregnancy with about 10% of the women in the first trimester and 36–50% in the third trimester having symptomatic disease. Overall, symptomatic disease occurs in 60–90% of pregnant women.<sup>18</sup> A recent study by Foxman et al.,<sup>19</sup> which included interviewing 2000 women, determined that the incidence of RVVC in the US is approximately 8% in women of reproductive age.

There has been an improved understanding of the epidemiology of candidal infections because of developments in typing methods involving serological techniques (serotypes A and B), DNA typing, and southern blot hybridization.<sup>20</sup> Serotype B is more commonly found in immunocompromised patients. It is the predominant type in Europe. Whereas, in the US, both types A and B are common, and in Hong Kong, serotype A strains predominated in blood culture isolates. The majority of the typing surveys have been done in patients with disseminated disease, including heroin addicts, who may have specific biotypes. Typing methods have confirmed that most of the recurrences in RVVC are caused by the same strain; the yeast may reside in protected rectal sites. *C. albicans* generally does not become resistant to antimycotics even after intermittent and prolonged courses of antifungal agents.<sup>21,22</sup>

In one study, 18 patients with RVVC were assessed with DNA probes and it was found that in sequential episodes, the strains were identical, sustaining the maintenance of the same strain. The isolates from oropharynx and vulvovaginal areas were also same or closely related in 80% of the patients. The isolates were the same in the male partners of 8 patients. These findings support the hypothesis that RVVC is due to vaginal relapse of a persistent yeast infection.<sup>23</sup>

In another study, a DNA probe was used to strain-type isolates from vagina and rectum in 121 women including 22 women with RVVC. Of the 78 women, who were culture positive,

22 women became culture negative after local application of clotrimazole, but again became culture positive within 12 weeks. Another 12 women remained culture positive at follow-up (persistent carriage). Women with asymptomatic persistent infection had significantly lower viable candidal counts at their post-treatment follow-up visit. Of the 66 women with positive cultures for *C. albicans* in both vagina and rectum, 52 had genetically identical isolates. This study also found that there was no evidence of resistance to either fluconazole or clotrimazole in immunocompetent persons with recurrent infection or persistent carriage of *Candida*.<sup>24</sup>

## MYCOLOGY

The most common human mycoses are caused by the genus, *Candida* and often cause opportunistic infections as these yeasts can exist as common commensals that colonize epithelial surfaces. *Candida*, classified as yeast, is a dimorphic fungus that forms budding blastoconidia, which elongate into pseudohyphae and these can develop into true hyphae. *Candida* is in the class of Blastomycetes but under the order Cryptococcales. More than 200 species have been classified, but there are less than 10 non-*C. albicans* species that are frequently associated with infections. These species can be identified by their colony characteristics, microscopy, biochemical reactions such as fermentation, assimilation of sugars, and growth in different nutrient media.<sup>25</sup> In a recent study, non-*C. albicans* species were isolated in 11% of women with vulvovaginal yeast carriage who reported to primary care hospitals. Various non-*C. albicans* species isolated were *C. glabrata* (69%), *C. parapsilosis* (9%), *C. krusei* (9%), *C. tropicalis* (6%), *C. cerevisiae* (5%), *C. kefyr* (1%), and *C. humicolus* (1%).<sup>26</sup> *C. albicans* grows on Sabouraud agar as shiny, cream-colored, yeasty-smelling, smooth-surfaced colonies. On wet-preparation microscopy, spherical budding yeast cells with pseudomycelium are seen. The germ tube test where the yeast produces hyphal germ tubes when incubated at 37°C in serum for 2 or 3 hours, is the classic diagnostic test. Chlamydospore formation on cornmeal polysorbate 80 agar at 22°C to 25°C in 48–72 hours confirms the identity.<sup>27</sup> The two genera *Candida* and *Torulopsis* have now merged and *C. glabrata* is the most common cause of non-*C. albicans* infections. *Saccharomyces cerevisiae* (bakers and brewers yeast) also causes clinical VVC. Non-*C. albicans* yeasts are often variable in their sensitivity to antimycotic agents and sensitivity tests are required, if there is complicated or recurrent disease. *Candida* transmission probably occurs through its yeast form that is present in asymptomatic infection. The pseudomycelial form is associated with invasion and symptomatic infection. The phenomenon of phenotypic switching is visible as different colony types appear white and opaque on culture. These have differences in their hyphal-forming capacity, generation time, and sensitivity to low and high temperatures. The yeast develops into a hypha with the expression of virulence genes that can encode hyphal wall protein; cyclic AMP plays a role through *C. albicans* cyclase-associated protein gene.<sup>28</sup> Switching may also enhance adhesion

and the secretion of pathogenic enzymes such as phospholipases, aspartate transaminases, and other proteinases.<sup>29</sup>

## **PATHOLOGY**

*Candida* most commonly causes superficial infection. It can also cause locally invasive disease or systemic infection. Superficial candidiasis is associated with swelling (edema), redness, and sometimes, superficial ulceration. Immunosuppressed patients may have locally invasive candidiasis, e.g., esophagitis, which may manifest as mucosal ulcerations with or without a pseudomembrane.

Microscopically, an acute inflammatory reaction occurs, which can be seen on hematoxylin and eosin, periodic acid-Schiff (PAS), and silver stain. These stains reveal oval yeasts as well as pseudohyphae, which along with necrotic debris, make up the typical vaginal wall white plaques of candidal infection. In ulcerated lesions with more localized invasion, there may be a pseudomembrane on top of the ulcer, excess of fibrin, pseudohyphae, and necrotic debris.<sup>30</sup>

## **PATHOGENESIS**

### **Microbial Pathogenesis**

#### **Adherence**

*C. albicans* has the greatest affinity for adhering to vaginal epithelial cells, followed by *Candida tropicalis* and *Candida parapsilosis*. Adherence is dependent on many factors including the local environmental milieu. These factors include the presence of other microorganisms that may be competing for cellular binding sites; nutrients such as glucose, the concentration of hormones, particularly estrogen, which increases the avidity of epithelial cells for *C. albicans*, and the presence of immunoglobulin A (IgA), which may interfere with adherence.<sup>31</sup>

Cell surface hydrophobicity of *C. albicans* is important in adherence. Germ tube formation is associated with a significant rise in cell surface hydrophobicity.<sup>32</sup> Initial adherence is dependent on unidentified receptors, adhesions related to fibronectin. The mannoprotein component on the yeast surface probably plays a role and is associated with impaired phagocytosis. Adherence leads to colonization and increased population density is associated with symptomatic/invasive disease.

#### **Invasion**

Germ tube hyphae have a different surface immunogenicity that could fool immune mechanisms and at the same time, potentiate invasion by production of multiple enzymes, mostly proteinases.<sup>22</sup> Proteinases break down peptide bonds, phospholipases enhance invasion, carboxyl phospholipases are proteolytic to keratinocytes, and aspartate proteinases are collagenolytic. These along with hyphae can actually lead to invasion through cells. Secreted aspartate transaminases are encoded by 10 different genes. The genes, which are important for infections of skin and mucous membranes, are

different from those important in systemic infections.<sup>33</sup> These enzymes may also break down local immunoglobulins.<sup>34</sup>

Fidel's group has studied the pathogenesis of candidiasis for decades often in experimental animals. A study using women as a live challenge model showed that asymptomatic women had a non-inflammatory response. Symptomatic women had an aggressive immune response with neutrophil infiltrates.<sup>35</sup>

Another group of researchers studied the levels of hyaluronan, an anti-inflammatory immune system activator released into vaginal secretions. *C. albicans* strains can produce hyaluronidase. Hyaluronan levels in a small group of women were shown to be increased in RVVC infections not on treatment, compared to controls and those on fluconazole. High levels were also associated with itching/burning or itching/discharge symptoms. The authors inferred that there may be 2 subsets of RVVC that may have implications for therapy.<sup>36</sup>

## **HOST-DEFENSE MECHANISMS**

### **Natural Barriers and Precipitating Factors**

The integrity of a mucosa with the stability of local factors is an important defense against invasion. Factors like pH (as germ tube formation is maximal at pH 6), the presence of glycogen (which is increased by estrogens, natural, cyclical, or iatrogenic), increased glucose levels (as in diabetes and high sugar intake), and high iron levels facilitate virulence. Other factors like physical trauma, increased moisture, occlusion (nappies, sanitary towels),<sup>37</sup> loss of normal microbial flora (post antibiotics or replacement with other organisms), and the use of steroids (that interferes with polymorph phagocytosis) may jeopardize the normal environment<sup>31,34</sup> allowing opportunism.

### **Humoral Immunity**

Although patients with IgA deficiency are not known to be particularly susceptible to candidal infections, humoral immunity does have some part to play in the initial local defenses. High levels of IgA can be found in infected patients, but they do not prevent colonization; therefore, there is no role for the use of gammaglobulins as treatment of RVVC.

In RVVC, 25–33% of women may be genetically predisposed. The non-secretors of Lewis blood group have greater than 3 or 4 times risk of developing RVVC. It is well known that hypersensitive candidal balanitis occurs in men, and it has been postulated that this phenomenon may play a role particularly in RVVC. Women with elevated immunoglobulin E show an increased amount of prostaglandin E2 in vaginal secretions, which is known to enhance *C. albicans* germ tube formation and reduce peripheral blood lymphocyte production.<sup>29</sup> Macrophages and neutrophils are important in protection against systemic invasive candidiasis.<sup>38</sup>

### **Cell-Mediated Immunity**

Cell-mediated immunity (CMI) is the most important host-defense mechanism against mucosal candidiasis. However, the

role of CMI in VVC and RVVC is now questioned because an inflammatory immune response may not be advantageous at a reproductive site.<sup>39</sup> There has always been conflicting evidence about the role of CMI and humoral antibody in RVVC. There may be a more important role for mucosal innate resistance. Recent studies have found that epithelial cells from saliva and vaginal lavages of healthy individuals inhibit the growth of *Candida in vitro*. To date, the evidence suggests that immunity to candidal infections is site-specific, compartmentalized, and involves innate and/or acquired mechanisms from systemic and/or local sources.<sup>40</sup> Studies in rodent models and in humans have emphasized the importance of a compartmentalized local vaginal response rather than a systemic response.

A study in 28 women with RVVC and 25 controls suggested that there was a partial T-cell dysregulation with higher gamma interferon production in RVVC patients. This may be exacerbated by the elevated levels of estrogens in the follicular phase of menstrual cycle. This correlates with the risk of clinical infection during this period.<sup>41</sup>

Some women respond to hyposensitization with *Candida* antigens given over the course of few weeks to months. This indicates a possible role of hypersensitivity reaction in the pathogenesis. Th1- and Th2-type responses cross-regulate each other, and if there is enough increase in antigenic load, there may be an induction of Th2-type response. This could inhibit the normal protection associated with the Th1-type reactivity. There may be a role for immunotherapy involving anticytokine reagents to reduce the Th2-type activity and promote Th1-type activity. Clinically, patients can present as a spectrum of disease, at one end with a hypersensitivity reaction with marked swelling and redness of the vulva associated with low yeast counts, and at the other end, patients who have an anergic response with high yeast counts, obvious vaginal plaques, and minimal edema and reaction.<sup>34</sup>

## CLINICAL DISEASE

### Spectrum of Disease

Candidal infections involve mucous membranes, but can also cause intertrigo, angular cheilosis at the edges of the mouth, paronychia, and onychomycosis (nail infections). In HIV/AIDS patients with immunocompromised status, esophagitis is a common problem; in post-transplant patients or in those with neutropenia, disseminated disease can occur. Although 20% of women carry *Candida* vaginally as a commensal, it is the most common cause of vaginitis in the tropics and it is at least 20 times more common than balanoposthitis.

### Uncomplicated and Sporadic VVC

This is usually caused by *C. albicans* in patients with no underlying predisposing factors including pregnancy. These patients have only mild-to-moderate symptoms.

### Patients Presenting with Vulval and Vaginal Pruritus

They may notice swelling and redness of the vulva with fissuring, particularly between the intravulval folds with accompanying external dysuria. They may notice a thick white curdy discharge and external dyspareunia. The itching is usually worse at night or after a shower. They often experience most of the symptoms premenstrually or after sexual activity.

On examination, the vulva may be edematous with visible adherent white discharge at the introitus and vestibular area. The vaginal mucosa is brightly inflamed. There may be evidence of acute fissuring or there may be a normal-looking external vulva. On speculum examination, a very inflamed vaginal epithelium with white plaques like 'cottage cheese' may be seen. In some women, there is a more watery or occasionally frank purulent discharge.

### Complicated VVC

This includes recurrent and severe VVC, VVC caused by non-*C. albicans* species, and VVC in women with uncontrolled diabetes, debilitation, or immunosuppression or those who are pregnant (see Table 48.1). RVVC is defined as 4 or more episodes of symptomatic VVC per year (at least one episode confirmed by culture).

There may be a rash with satellite micropustules around the outer labia and redness and involvement of the perianal area (Fig. 48.1). Women with post-thrush vestibulitis may have tender

**Fig. 48.1:** A patient with complicated vulvovaginitis, predisposed by long-term use of broad spectrum antibiotics. Note swelling and erythema of labia and maceration of intertriginous skin.

areas around the hymenal ring particularly between 3 o'clock and 9 o'clock when touched with a white cotton tipped swab. There may be increased redness and increased vascularity on vulvoscopy around the areas of vestibulitis. There may be involvement of the periurethral area and also infection of the urinary tract. In candidal vulvovaginitis, both a clinical and a laboratory diagnosis should be made. In a study on the accuracy of a candidal vaginitis clinical diagnosis, compared with a positive specific DNA probe, it was shown that the clinical diagnosis had a sensitivity of 83.3% and specificity of 84.8%. Despite the use of standardized clinical criteria in this study, diagnosis and therefore treatment may be inaccurate.<sup>42</sup>

## PREDISPOSING FACTORS

Many of these have been mentioned previously including the use of antibiotics, which is usually a short-term risk factor in the first episode, but can also predate RVVC. In one study, the increasing duration of antibiotic use was directly related to an increased prevalence of VVC, and the common indications for antecedent antibiotic use were urinary tract infections and upper respiratory tract disease.<sup>43</sup>

Estrogens are associated with cyclical candidiasis (preperiod). Candidiasis is associated with hormone replacement therapy and also with pregnancy, particularly in the third trimester. The old, high-dose (50 µg) estrogen oral contraceptive pill predisposes to VVC. Progesterone contraceptives and lactation are probably protective.

Estrogen increases the formation of glycogen in epithelial cells, which is a carbon source for yeasts. It also increases the adherence of *Candida* to the epithelial cells and enhances yeast mycelium formation.

In postmenopausal women, there may be underlying risk factors for VVC like hormone replacement therapy, uncontrolled diabetes mellitus, immunosuppression from HIV, broad-spectrum antibiotic therapy, douching, or the use of perfumed, feminine hygiene products.<sup>44</sup> Tamoxifen treatment in postmenopausal women has been found to be associated with RVVC, and in one study, all patients were infected with *C. glabrata*.<sup>45</sup>

General predisposing factors include occlusion and maceration of the skin which is associated with the use of tight, vinyl cycling pants and non-cotton, tight clothing in the tropics.<sup>17</sup> The incidence increases with the onset of sexual activity, the use of sponges, and IUCDs.<sup>23</sup>

Many women with RVVC tend to be atopic. In a study of 95 patients with RVVC and 100 controls, 74% of the patients had allergic rhinitis in comparison to only 42% in the control group. There was no association between RVVC and asthma; however, there was an association with skin test positivity to inhalant allergens and to *C. albicans*. There was a high incidence of family history of allergies in patients.<sup>46</sup>

Among other predisposing factors, the role of iron, vitamin A, and zinc in RVVC is controversial. Unbound iron enhances *C. albicans* growth and iron deficiency has been described with oral

candidiasis. Deficiency of vitamin A may affect keratinization, and protein deficiency affects host defenses. Zinc deficiency (from chronic gut disease or alcoholism) has also been associated with increased oral candidiasis and RVVC.

## VVC IN HIV-SEROPOSITIVE WOMEN

For many years, oral and esophageal candidiasis have been increasingly recognized in HIV-seropositive patients. VVC has also been described in HIV-positive women. This was not surprising with the degree of immunosuppression and the broad-spectrum antibiotic treatments for opportunistic infections in these patients. In effect, RVVC was later described as a presenting marker for underlying HIV infection but is not now thought to be an indication for HIV testing. In a meta-analysis of 39 studies reporting the effect of genital tract infections on the detection of HIV 1, it was found that patients with *Candida* were more likely to have HIV 1 detected (OR 1.8, 95% CI 1.3–2.4).<sup>47</sup>

A study assessing the effect of treatment of vaginal infections on the shedding of HIV in 98 patients with VVC showed that the vaginal HIV 1 RNA decreased after treatment for candidiasis. *Trichomonas vaginalis* treatment showed the same finding but this was not the case for BV. Treatment of VVC resulted in a 3.2-fold reduction in the concentration of HIV in vaginal secretions and a 3-fold decrease in the likelihood of detecting HIV 1 infected cells.<sup>48</sup>

In another prospective study on 205 HIV-positive women, it was shown that the risk of developing symptomatic VVC increased 6.8 times for women with CD4+ cell count less than 200 cells/µL.<sup>49</sup> Another study looking at oropharyngeal candidiasis showed that oral disease presents earlier in HIV-seropositive patients with higher CD4+ cell count compared to those with VVC. This study also suggested that the protection against oropharyngeal candidiasis or VVC was more dependent on factors in the local mucosal immune milieu than systemic CMI.<sup>41</sup>

## LABORATORY INVESTIGATIONS

### pH Measurement

The pH of vaginal discharge in VVC is low, between 3 and 4.5, which distinguishes it from other causes of vaginitis. Swabs should be taken from the lateral vaginal wall and placed on the pH paper. Contamination with blood, cervical mucus, semen, and local medications, e.g., antifungal creams, should be avoided as it may affect the pH of the secretions.

### Microscopic Examination

Wet mount of saline preparation should be routinely done to exclude clue cells and trichomonads. A sample of vaginal secretion is taken with a loop and mixed into a drop of saline on one slide and a drop of 10% KOH on another, cover slips placed on top and viewed under low-power microscopy. In 40–60% patients, budding yeasts and lengths of pseudohyphae may be seen.

## Culture

The majority of symptomatic patients will have high counts more than  $10^3$  blastospores per mL of vaginal secretion. Swabs from the lateral wall of the vagina can be placed in Amies transport medium or can be directly plated on a Sabouraud plate. In patients who have small number of yeasts because of partial treatment or in those who are hypersensitive to small amounts of antigen, the yield can be improved by taking vaginal washings or inoculating swabs directly into a broth media with antibiotics. Wherever possible, cultures should always be done to confirm the diagnosis, particularly if there is a negative wet preparation examination. Cultures may be necessary in complicated disease, where non-*C. albicans* strains are suspected and where sensitivity testing against antifungals is necessary.

New chromogenic agar media for the differentiation of *Candida* species are useful in situations where mixed infections are suspected or there is inadequate response to usual therapy (Fig. 48.2).<sup>50</sup>

## Cervical Smear (Pap Smear)

A study on the clinical significance of detecting *Candida* on Pap smears showed that there was marked inflammation associated with symptomatic disease, but no association with the type of yeast seen (blastospores or hyphae) or number of *Candida* organisms present.<sup>51</sup>

## Polymerase Chain Reaction (PCR)

It has been suggested that recovery of fewer than 10 yeast colonies from a vaginal swab is unlikely to be pathognomonic for symptomatic candidiasis. Enrichment broth cultures for *Candida* may be over-sensitive and fail to distinguish between

the true infection and commensal carriage in most cases. Thus, PCR, a highly sensitive laboratory test, has little value in the diagnosis of uncomplicated candidal vulvovaginitis.<sup>52</sup>

In a study of 50 women with RVVC and 45 women with one or less episodes of vaginitis, it was shown that *Candida* was more easily detectable in those with RVVC even when they were asymptomatic. The culture, wet mount and Gram stain, had a sensitivity of 66.6% in comparison with PCR.<sup>53</sup> One hundred and four women with RVVC had vaginal secretion cultured and tested by PCR. Culture was positive in 31 women (29.5%) and 44 women (42.3%) had a positive PCR for *Candida* species. In 13 women (12.5%), only PCR was positive.<sup>54</sup>

The isolation of yeasts between sexual partners using PCR has revealed identical strains in 8 out of 15 couples.<sup>55</sup> *C. albicans* DNA in serum has been measured by PCR for the diagnosis of invasive candidiasis and PCR with dot blot hybridization has been used to identify rare *Candida* species and other yeasts.

## DIFFERENTIAL DIAGNOSIS OF CLINICAL CANDIDIASIS

At the initial presentation in the sexually active patient, it is essential to screen for all causes of discharge, including upper genital tract infection by taking cervical swabs for Chlamydia, gonococci and, if indicated, herpes. Also, there should be exclusion of other causes including BV and trichomoniasis by suitable laboratory tests. Although the pH and microscopy may often exclude these, there are often mixed infections with mixed signs and symptoms, so full screening including culture for *T. vaginalis* is preferred. In fact, BV is quite commonly found in patients with RVVC.

The differential diagnosis of RVVC includes infective causes, like recurrent BV, recurrent trichomoniasis, unrecognized recurrent genital herpes, suprapubic lice, genital scabies and non-infective causes like, allergic and chemical vulvitis, contact dermatitis, atrophic vaginitis, atrophic vestibulitis, idiopathic vestibulitis syndrome, desquamative inflammatory vaginitis, erosive lichen planus, lichen sclerosus, dermatoses (eczema, atopy, psoriasis), and physiologic leucorrhoea.<sup>55</sup>

## MANAGEMENT

### Uncomplicated VVC

Many regimens have been recommended in various guidelines (Table 48.2).<sup>56–59</sup>

Most women have uncomplicated disease with cure rates with antifungal medications of more than 80%. Local imidazole treatments in the forms of ovules, pessaries, tablets, creams for one, three, or six days have relatively equal efficacy. However, instant treatment does not work instantly. These preparations probably stay inside the vagina for some days. External cream is useful if external genitalia are involved.

In moderate cases with severe edema and fissuring, there may be a period of 1–2 weeks before all symptoms get resolved. The area can be quite extensive and the patient should be advised to rest

**Fig. 48.2:** Use of *Candida* chromogenic media (CHROMagar™). Inoculated with *C. albicans*, green colonies; *C. krusei*, flat pink colonies; *C. tropicalis*, blue colonies after 48 hours incubation; other *Candida* species—white to pink. (Mycology preparation & photography by Karen Rogers and Wendy McKinney. Mycology Reference Laboratory, LAB+ Auckland Hospital, New Zealand).

**Table 48.2:** Recommended Regimens for Uncomplicated Vulvovaginal Candidiasis

<b>A. CDC Guidelines (2010)<sup>10</sup></b>
<i>Over the Counter Intravaginal Agents</i>
Butoconazole 2% cream 5 g intravaginally daily for 3 days, or
Clotrimazole 1% cream 5 g intravaginally daily for 7–14 days, or
Clotrimazole 100 mg vaginal tablet daily for 3 days, or
Miconazole 2% cream 5 g intravaginally for 7 days, or
Miconazole 4% cream 5 g intravaginally for 3 days, or
Miconazole 100 mg vaginal suppository, one suppository for 7 days, or
Miconazole 200 mg vaginal suppository, one suppository for 3 days, or
Miconazole 1200 mg vaginal suppository, one suppository for 1 day, or
Tioconazole 6.5% ointment 5 g intravaginally in a single application.
<i>Prescription Intravaginal Agents</i>
Butoconazole 2% cream (single dose bioadhesive product), 5 g intravaginally for 1 day, or
Nystatin 100,000-unit vaginal tablet, one tablet for 14 days, or
Terconazole 0.4% cream 5 g intravaginally for 7 days, or
Terconazole 0.8% cream 5 g intravaginally for 3 days, or
Terconazole 80 mg vaginal suppository for 3 days
<i>Oral Agent</i>
Fluconazole 150 mg oral tablet, one tablet in a single dose
<b>B. WHO Guidelines (2003)</b>
Miconazole or clotrimazole, 200 mg pessary intravaginally daily for 3 days, or
Clotrimazole, 500 mg pessary intravaginally in a single dose, or
Fluconazole, 150 mg orally as a single dose.
<i>Alternative regimen</i>
Nystatin, 100,000 unit vaginal tablet, one tablet daily for 14 days
<b>C. UK National Guidelines on the Management of Vulvovaginal Candidiasis (2007)</b>
Clotrimazole, pessary, 500 mg stat <sup>†</sup>
Clotrimazole, pessary, 200 mg x 3 nights <sup>†</sup>
Clotrimazole, pessary, 100 mg x 6 nights <sup>†</sup>
Clotrimazole, vaginal cream, (10%) 5 g stat <sup>†</sup>
Econazole, pessary, (ecostat 1) 150 mg stat <sup>†</sup>
Econazole, pessary, 150 mg x 3 nights <sup>†</sup>
Fenticonazole, pessary, 600 mg stat <sup>†</sup>
Fenticonazole, pessary, 200 mg x 3 nights <sup>†</sup>
Isoconazole, vaginal tablet, 300 mg x 2 stat <sup>†</sup>
Miconazole, ovule, 1.2 g stat <sup>†</sup>
Miconazole, pessary, 100 mg x 14 nights <sup>†</sup>
Nystatin, vaginal cream, (100,000 units) 4 g x 14 nights
Nystatin, pessary, (100,000 units) 1–2 x 14 nights
<i>Oral Therapies</i>
Fluconazole, capsule, 150 mg stat <sup>§</sup>
Itraconazole, capsule, 200 mg bd x 1 day <sup>§</sup>
<i>Treatment of Recurrent Vulvovaginal Candidiasis</i>
Induction, Fluconazole, § 150 mg capsule every 72 hours x 3 doses
Maintenance, Fluconazole, § 150 mg capsule once a week for 6 months
<i>Alternatively</i>
Induction topical imidazole therapy can be increased for 10–14 days
Maintenance:
Clotrimazole, 500 mg, pessary, once a week
Fluconazole, § 50 mg capsule daily
Itraconazole, § 50–100 mg capsule daily
Ketoconazole, § 100 mg capsule daily
<b>D. European STD Guidelines (2001)</b>
<i>Topical Therapies</i>
Clotrimazole, vaginal tablet 500 mg once or 200 mg once daily for 3 days, or
<i>Oral Therapies</i>
Fluconazole, 150 mg as a single dose, or
Itraconazole, 200 mg twice a day for one day.

<sup>†</sup>Over-the-counter preparations.<sup>†</sup>Effect on latex condoms and diaphragms not known.<sup>†</sup>Product damages latex condoms and diaphragms.<sup>§</sup>Avoid in pregnancy/risk of pregnancy and breastfeeding.

the “injured limb” and avoid sexual activities. Otherwise, relapse can occur requiring more prolonged courses of local antifungal therapy. Often, systemic (oral) therapy such as single dose of 150 mg of fluconazole, repeated after 3 days or itraconazole 200 mg a day for 2 days helps.

## Complicated VVC

Before initiating pharmacotherapy, every effort should be made to eliminate underlying or predisposing factors when recognized.<sup>58</sup> In patients with diabetes, hyperglycemia should be controlled. However, cessation of oral contraceptive pills rarely results in reduction of frequency of clinical episodes. Removal of IUCDs is of variable use and not indicated. In women with RVVC precipitated by frequent use of systemic antibacterial agents, it is unnecessary to put the patient on long-term maintenance regimen and individual episodes can be prevented by the use of episodic prophylactic azole agents in conjunction with the needed antibacterial course.<sup>58</sup> Unfortunately, in the majority of the patients with RVVC, no underlying precipitating factor is evident. Identifying the species of the yeast present and exclusion of mixed yeast infections (10%) are necessary. Patients with non-*C. albicans* species should be managed accordingly (see below).

Each case of RVVC should be treated with an initial induction therapy followed by a maintenance regimen. The 2006 CDC Guidelines<sup>10</sup> for treatment of RVVC recommend a short course of oral or topical azole therapy to treat each individual episode. Many specialists recommend a longer duration of initial induction therapy (e.g., 7–14 days of topical therapy or a 150 mg, oral dose of fluconazole repeated 3 days later) to achieve mycologic remission before initiating a maintenance regimen. A multicenter double-blind study of initial induction therapy in 565 women with complicated VVC has shown that 150 mg fluconazole given stat, then repeated three days apart was adequate to achieve control. Women with recurrent, but not severe, infection responded well to a single dose of 150 mg fluconazole.<sup>60</sup>

Sobel's multicenter, prospective, randomized study on maintenance fluconazole therapy for RVVC on 387 women, half on placebo, used the induction of 150 mg fluconazole, 72 hours apart. This was followed by 150 mg pulses weekly. At 6 months, 90.8% were disease free (35.9% –placebo group); at 9 months, 73.2% (27.8%); and 12 months, 42.9% (21.9%).<sup>61</sup>

A recent study used an induction dose of 600 mg of fluconazole in 117 women, then a dosage of 200 mg weekly for 2 months, then 200 mg every 2 weeks for 4 months, and 200 mg monthly for 6 months. One hundred and one women (90%) were disease free at 6 months and 80 (77%) after 1 year.<sup>62</sup>

Based on available data, therapy for VVC in HIV-infected women should not differ from that for seronegative women. Fluconazole, 200 mg weekly dose as a prophylactic therapy is not recommended for routine primary prophylaxis in HIV-infected women in the absence of RVVC.

Failure of these regimens regardless of the duration of treatment occurred with non-*C. albicans* species. If these species are isolated, full-sensitivity assessment should be carried out so that dosage

**Fig. 48.3:** Sensititre minimum inhibitory concentration plate showing sensitivity of *C. glabrata* isolate to six antifungals. (NCCLS reference method for broth dilution antifungal susceptibility testing of yeasts). Red—positive growth; blue—negative growth. A, Growth control; B, Amphotericin B, 1.0 (sensitive); C, Fluconazole, 16 (dose dependant); D, Itraconazole, 0.5 (dose dependent); E, Ketoconazole, 0.5 (sensitive); F, 5-flucytocine, 0.03 (sensitive); G, Voriconazole, 0.25 (sensitive).

can be tailored accordingly (Fig. 48.3). A two-week regimen can be tried on increased dosage, e.g., 450 mg daily.

#### Fluconazole Resistance in RVVC

Fluconazole-resistant strains of *C. albicans* are rare in VVC. Fluconazole-resistant infection can occur more frequently in immunosuppressed patients with oropharyngeal and esophageal candidiasis. Fluconazole resistance may be due to the drug being expelled through the membrane channels.

#### VVC and RVVC in Pregnancy

The oral imidazoles are contraindicated in pregnancy. There is evidence of teratogenicity from the long-term use of high dose of fluconazole.<sup>63</sup> Hypoplastic left heart syndrome was found to be an increased risk (OR 2.30; 95% CI 1.04, 5.06) in 7 cases out of 176 pregnant women on antifungal drugs (4581 controls). Three had used miconazole, 1 terconazole, 1 ketoconazole, and 2 antifungal unknown.<sup>64</sup> Extended courses of topical azoles (10–14 days) are usually effective in problematic cases. RVVC sometimes disappears in pregnancy, but in some women, it may persist. The use of clotrimazole pessaries, 500 mg intravaginally every one or two weeks can control symptoms.

#### Non-*C. albicans* VVC

*C. glabrata*, (a small, non-budding yeast) is the second most common yeast associated with RVVC and is 10–100 folds less susceptible to all azoles.<sup>55</sup> Many strains have a higher minimum inhibitory concentration and may respond to higher dosages of oral antifungals. *C. glabrata* along with *C. tropicalis* may be resistant to fluconazole, predominately in HIV positive women.<sup>65</sup> The only drug more active against *C. glabrata* than *C. albicans* is flucytosine. Intravaginal boric acid, 600 mg/day for 14 days will result in eradication of *C. glabrata*

in approximately 70% of patients.<sup>66</sup> Flucytosine as a 17% solution, given intravaginally, is a good alternative.

On microscopy *C. tropicalis* appears as ellipsoidal budding cells with plenty of pseudomycelia, which are poorly branched. It is found increasingly in patients with impaired immunity and has variable sensitivity to fluconazole.

*C. krusei* is inherently resistant to fluconazole.<sup>67</sup> On microscopy, it has budding cells, which are ellipsoidal to cylindrical; pseudomycelium is often present.

#### New Developments in Antimycotic Agents

The absorption of the capsule formulation of itraconazole is variable especially with hypochlorhydria, but swallowing with non-diet Coca Cola may help. The new itraconazole cyclodextrin oral solution with better absorption has similar clinical response rates to fluconazole when it is being used in Candida esophagitis in HIV infection.<sup>65</sup> The cost of this preparation has precluded its use in RVVC. Similarly, the new azole anti-fungal agent, voriconazole, is highly expensive. Voriconazole blocks the sterol biosynthesis and alters the morphology of Candida species and has been shown to be more effective against non-*C. albicans* strains as well as fluconazole-resistant *C. albicans*. Fifteen women suffering from acute VVC and 17 from RVVC showed a clinical cure of 66% and mycological cure of 75% at one month, using oral posaconazole one 200 mg dose.<sup>68</sup>

#### Other Treatments

A randomized, double-blind, placebo-controlled study of 55 women with VVC treated with 150 mg fluconazole followed by either 2 capsules of placebo or 2 capsules of probiotic daily (a mixture of lactobacilli) for 4 weeks had less discharge and other symptoms and less culture-positive yeasts on follow-up.<sup>69</sup>

In another study, agar dilution tests were performed to assess the antifungal potential of boric acid on fluconazole-sensitive and fluconazole-resistant *C. albicans*. Minimum inhibitory concentrations ranged from 1563 to 6250 mg/L, i.e., concentrations available vaginally and boric acid showed a fungistatic to fungicidal effect.<sup>70</sup>

#### Important Considerations

- The non-*C. albicans* strains of yeasts are identified using biochemical tests, e.g., API 20C, Bio Merieux. Determination of minimum inhibitory concentration is recommended using a microbroth dilution method with interpretive break points, as in the guidelines of the National Committee for Clinical Laboratory Standards (NCCLS).<sup>71</sup> A quantitative reverse transcriptase-PCR-based azole sensitivity test has been developed to test for *C. glabrata* resistance to azoles.<sup>72</sup> Multi-azole cross-resistance can occur in these isolates. These have been particularly described in HIV-positive patients with reduced CD4+ counts (less than 50 cells/mL).

- Terconazole cream (available in the US) has been recommended as first-line treatment for non-*C. albicans* vaginal infections. In one study on 20 patients, 14 (56%) had mycological cure.<sup>73</sup>
- Non-*C. albicans* VVC has been treated with boric acid powder in a double-blind trial using daily intravaginal gelatin capsules with 600 mg of boric acid versus identical capsules with 100,000 units of nystatin for 14 days. Cure rate with boric acid capsules was 72% at 30 days, whereas with nystatin, it was 50%. Blood boron analysis indicated little absorption from the vagina with blood concentrations of less than 10 µg/L during the use of one or two boric acid capsules per day. Boric acid powder was used because boric acid crystals occasionally cause male dyspareunia.<sup>74</sup>
- Maintenance therapy with topical boric acid was compared with oral itraconazole in the treatment of RVVC in a prospective non-randomized study. The response to treatment was the same in both groups. After 6 months, the therapy was discontinued, and at the 12th month visit, 54% had relapsed.<sup>75</sup> The toxicity profile of long-term maintenance therapy of boric acid is unknown.
- *S. cerevisiae* has variable sensitivity to antifungals.<sup>76</sup>
- Strains resistant to oral azoles, can be treated with boric acid or nystatin vaginal cream (100,000 units nocte as pessaries). Aqueous gentian violet 1% has also been used in resistant cases.<sup>77</sup> Topical flucytosine has been described as being useful in some cases and a formulation mixed with amphotericin B for the use in refractory VVC caused by *C. glabrata* has been described.<sup>78</sup>

## Oral Azoles—Systemic Toxicity, and Drug Interactions

Maintenance dose therapy with oral azoles, such as itraconazole and fluconazole, works because of the prolonged half-life (4–5 days) of these drugs on usual dosage regimens. These triazoles have been associated with clinically significant drug interactions. Itraconazole and fluconazole in high doses are inhibitors of cytochrome (CYP) P3A4. These cytochrome P-450 enzymes are a family of catalytic hemoproteins that are important in the metabolic transformation of many drug substrates. Reduced CYP activity results in decreased metabolism of the substrate drug with an increase in the bioavailability and potential drug toxicity.

Care should be taken if high doses of fluconazole are mixed with drugs with extensive first-pass metabolism such as astemizole, cisapride, or drugs with a narrow therapeutic window, such as warfarin, digoxin, phenytoin, and sulfonylureas. Care should be taken when itraconazole is prescribed with hepatotoxic drugs. Life-threatening cardiac arrhythmias might follow the combined use of high-dose fluconazole or itraconazole, and astemizole, cisapride; and the new generation H1 antihistamines. Other drugs requiring monitoring include cyclosporine, felodipine, and quinidine.<sup>79</sup>

## Acute Candidal Balanoposthitis

Balanitis occurs in about 10% of male genitourinary clinic attendees; the most common cause is candidiasis. The foreskin is often involved in the uncircumcised men.

### CLINICAL PRESENTATION

#### Symptoms

The patient may complain of a rash involving the glans penis or the prepuce, which is itchy, swollen, and red. Occasionally, there may be some discharge, mild dysuria, and dyspareunia. Symptoms may occur within an hour of sexual activity (hypersensitivity reaction) or within 24–48 hours post-exposure (candidal infection). This may be a relapsing recurrent condition, which can be disquieting for the patient. It is often acquisition from an infected female partner or be secondary to a low-grade skin condition, i.e., eczema or seborrheic dermatitis.

#### Signs

There may be erythema and swelling with a macular/papular rash of the glans penis and foreskin and superficial ulceration. A white subpreputial discharge, increased skin markings, fissuring of the glans and foreskin, and occasionally regional lymphadenopathy may be present.

### INVESTIGATIONS

A swab can be taken from the subpreputial area, glans, or urethra, and spread on a slide for a gram stain. It can be sent in transport medium or inoculated immediately onto Sabouraud dextrose media. It is wise in certain populations and age groups to do a urine analysis for glucose.

Where there is excessive fissuring or painful ulcers, a swab for herpes should be taken. Likewise, if the ulcerations are really atypical, a dark-ground examination for treponemes or smear and culture for *Haemophilus ducreyi* should be considered.

### MANAGEMENT

Non-specific balanoposthitis can be part of low-grade skin disorders like seborrheic dermatitis and contact allergy with colored or perfumed agents where *Candida* can be opportunistic.

Therefore, salt-water baths (1 pint of warm water to a teaspoon of ordinary salt) twice daily are recommended along with avoidance of soaps and bath additives.

Clotrimazole cream, 1% can be applied locally twice a day for at least a week. A 1% hydrocortisone and antifungal cream, like miconazole, can also be used. Alternatively, fluconazole 150 mg capsule/tablet orally stat can be advised if patient is allergic to imidazoles. This eradicates infection of the urethral meatus, inaccessible by creams or nystatin cream.

In patients, where contact allergic dermatitis is suspected, aqueous cream as soap substitute should be prescribed.

NB: If balanoposthitis persists for more than 6 weeks, a biopsy should be considered to exclude other causes including penile intraepithelial neoplasia, Zoon's balanitis (plasma cell balanitis), or erythroplasia of Queyrat.

### Summary

Vulvovaginal candidiasis is a common, debilitating genital condition that is often misdiagnosed and poorly managed. In recurrent disease, diagnosis of the yeast involved, as well as exclusion and treatment of any underlying condition is essential. Although preparations of local antifungals are many; they all have similar efficacy. Systemic antifungals are few and sometimes non-*C. albicans* strains are resistant to them, requiring further laboratory evaluation. Candidal Balanoposthitis, especially when recurrent, can be perplexing and upsetting. Reassurance and exclusion of underlying conditions, where possible, is important, although short-term local therapy of an antifungal and low-dose hydrocortisone mixture is usually effective.

# Trichomonas Vaginalis Infections

Barbara Van Der Pol

# 49

## Introduction

*Trichomonas vaginalis* is a sexually transmitted protozoan parasite that invades genital epithelia and may cause trichomoniasis in women and urethritis in men. The World Health Organization estimates that approximately 174 million cases of trichomoniasis occur globally each year.<sup>1</sup> This is more than the estimated number of chlamydial and gonococcal infections combined. Approximately 7–8 million cases are estimated to occur annually within the US alone. These estimates are for overt, symptomatic disease and cannot account for asymptomatic infections. Although this pathogen is recognized as a sexually transmitted infection (STI), unlike infections caused by *Chlamydia trachomatis* or *Neisseria gonorrhoeae*, reporting of trichomonas is not required by public health entities such as the Centers for Disease Control and Prevention.<sup>2</sup> As a result of this lack of reporting, it is difficult to estimate the actual prevalence of *T. vaginalis* infection.

This highly prevalent pathogen predominately affects women and may play a role in development of upper genital tract complications and cervical cancer, lead to adverse outcomes of pregnancy, and increase risk of HIV acquisition or transmission. Public health practitioners need to be aware of the likelihood of co-infection with other STIs, diagnostic test performance, and the appropriate treatment strategies in order to manage patients effectively. Each of these aspects of *T. vaginalis* will be presented in detail in the following sections.

## Biology and Pathogenesis

*T. vaginalis* is a flagellated protozoan that is highly motile (Fig. 49.1). Trichomonads, which are approximately the size of lymphocytes (15–25  $\mu\text{m}$  in length), have several long flagella that are involved in motility as well as an undulating membrane on one side of the organism that is clearly visible with light microscopy. *T. vaginalis* is strictly anaerobic and can survive in a variety of pH conditions ranging from highly acidic (pH 3.5), which is common during bacterial vaginosis, to basic (pH 8.0). As a result of sensitivity to atmospheric oxygen, drying conditions, and temperatures below 35°C, *T. vaginalis* does not survive *ex vivo*

for extended periods (greater than a few hours). Organisms lose motility quickly at room temperature.<sup>3</sup> Therefore transmission by means other than sexual contact is rare.

Upon entry into the vaginal milieu, *T. vaginalis* encounters the mucous layer that is the first line of defense from microbial colonization. Trichomonads produce enzymes that degrade mucin, the major component of mucous, thus allowing the organisms to come into contact with the cells of the vaginal epithelium.<sup>4</sup> Trichomonas also produces adhesins that enable attachment of the pathogen to the cell surface of vaginal epithelium. These adhesins are upregulated during times of high iron concentration. This mechanism may allow trichomonads to remain adhered to cells during menses.<sup>5</sup> Contact with epithelial cells results in their destruction and recruitment of inflammatory cells to the vagina, resulting in vaginal discharge. However, there are many factors that influence the level of cytotoxicity and local immune response. As a result, infection can cause a range of outcomes from completely asymptomatic disease to heavy discharge, odor, and itching.

Trichomonads themselves are susceptible to infection by a double stranded RNA virus that may influence the virulence of

**Fig. 49.1:** *T. vaginalis* from *in vitro* culture. Trichomonads stained with Giemsa stain (from [www.cdc.gov](http://www.cdc.gov)). Arrows show the flagella and asymmetrically located undulating membrane.

trichomonas.<sup>6</sup> Studies have shown that this virus is present in as many as 75% of patient isolates obtained from STD clinic attendees,<sup>7</sup> suggesting that the virus-infected trichomonas may have a survival advantage when in humans. Interestingly, isolates with the virus may be less likely to be resistant to metronidazole.<sup>8</sup>

Trichomonas is capable of phagocytosis of microbes commonly found in the vaginal environment including lactobacilli<sup>9</sup> and *Mycoplasma hominis*.<sup>10</sup> Lactobacilli are known to play a key role in vaginal health, while *M. hominis* has been linked with vaginal and cervical discharge syndromes as well as upper genital tract complications. The impact of interaction between *T. vaginalis* and these organisms is unknown. For an excellent review of the biology of trichomonas see Petrin and colleagues.<sup>11</sup>

## Epidemiology

The epidemiology of trichomonas is poorly understood for several reasons. First, since this infection is not monitored by public health agencies, there are few sources of reliable, population-based data. In studies that have reported testing in both men and women, the prevalence in women is 4–5 fold higher than in men. Second, despite evidence to the contrary, trichomonas infection is commonly believed to result in symptomatic disease in women although it is recognized that men rarely have overt disease.<sup>12</sup> Asymptomatic infection is widely considered to be a nuisance rather than a threat to reproductive health so screening in asymptomatic populations is uncommon. Thus, the majority of people tested for trichomonas are women with symptoms or attending an STD clinic that routinely provides such testing. Additionally, prevalence data are available from studies of HIV and STI studies in resource-constrained areas of the world such as sub-Saharan Africa. As a result, reports of trichomonas prevalence may represent populations at elevated risk (i.e., symptomatic women or women from STI endemic regions of the world) and should be considered in the appropriate context. Finally, as will be described below, the diagnostic methods used to identify trichomonal infection vary widely in sensitivity. Use of insensitive tests results in under-reporting of infections. For those women who are evaluated for the presence of *T. vaginalis*, as many as 50% of cases may be missed depending on the diagnostic method used. This lack of detection of infection would suggest that in some cases, even in high-risk populations, the prevalence may be significantly under-reported. Therefore, despite reports of prevalence ranging from 2 to 47%, it is unclear whether these estimates over- or under-represent the true prevalence of trichomonas within generalized populations.

Studies of the epidemiology of *T. vaginalis* infection have described risk factors similar to those identified for other STIs (for review see Johnston and Mabey<sup>13</sup>). These include infection with other STIs, previous infection with *T. vaginalis*, lower socioeconomic status, residence in a correctional facility, and sexual behaviors that increase risk of infections. These behaviors include

higher numbers of sexual partners, inconsistent condom use, sex in exchange for money or drugs, and intravenous drug use. Patients with any of these risk factors should be considered for evaluations of infection with trichomonas. Higher prevalence rates have often been reported in Black compared to White populations in the US; however, race is likely to be a surrogate for underlying factors in these studies. Finally, unlike the classic age distribution seen with *C. trachomatis*, and to a less dramatic degree with *N. gonorrhoeae*, *T. vaginalis* prevalence appears to increase with age.<sup>14</sup> In a multisite study performed in the US using DNA-based diagnostic testing, the peak age for infection was 40–44 years (Fig. 49.2).<sup>15</sup> A large, retrospective population-based study in China also demonstrated peak prevalence in women aged 35–45 years.<sup>16</sup> The difference in age-specific prevalence rates may be an artifact of long-term carriage and under-diagnosis of trichomonas that results in a cumulative prevalence rate. If untreated long-term infection were the only cause of increased age-specific prevalence, this would predict a steady increase throughout all age groups. However, all studies that have examined age have found that prevalence rates decline after age 50. Changes in prevalence may be related to changes in susceptibility as a result of hormonal or other changes in the vaginal micro-environment as women age. More research is clearly needed to improve our understanding of the biological factors that may affect women's risk of infection with *T. vaginalis*.

The most informative estimate of prevalence and risk factors in the United States was collected as part of a study of adolescent and adult health in a nationally representative sample of people

**Fig. 49.2:** Age-specific prevalence of *C. trachomatis*, *N. gonorrhoeae* and, *T. vaginalis*. The age-specific prevalence for *C. trachomatis* (CT), *N. gonorrhoeae* (GC), and *T. vaginalis* (TV) are shown from a multisite study of 1923 women. Gonorrhea rates are slightly higher in young women while chlamydia rates show the typical pattern of a definite peak for women less than 30. In the same women, trichomonas infection peaked in 35–50 year olds.

**Table 49.1:** Epidemiologic Risk Factors for *T. vaginalis* Infection in Women\*

	Category	Prevalence (98% CI)	P
Age (years)	14–19	2.1 (1.3–3.4)	0.076
	20–29	2.3 (1.3–4.0)	
	30–39	4.0 (2.5–6.5)	
	40–49	3.6 (2.3–5.7)	
Race	Non-Hispanic White	1.3 (0.7–2.3)	<0.001
	Non-Hispanic Black	13.3 (10.0–17.7)	
	Other	2.7 (0.9–8.3)	
Education	Less than high school	6.3 (4.4–8.9)	<0.001
	High school	4.7 (1.2–3.0)	
	More than high school	1.9 (1.2–3.0)	
Poverty index ratio	0–1.85	5.4 (3.6–8.2)	<0.001
	1.851–3.5	2.7 (1.7–4.4)	
	>3.5	0.9 (0.5–1.9)	

\*Adapted from Sutton MY, Sternberg M, Koumans EH, et al.<sup>18</sup>

aged 14–49 (NHANES). From this data set the prevalence rates of *C. trachomatis*, *N. gonorrhoeae*,<sup>17</sup> and *T. vaginalis*<sup>18</sup> in women were estimated to be 2.5% (95% CI 1.8–3.4%), 0.3% (95% CI 0.2–0.4%), and 3.1% (95% CI 2.3–4.3%), respectively. The strengths of these data are the large sample size (2000–3500 participants), the representative sampling design and the use of highly sensitive DNA-based diagnostic testing for all three organisms. These data support the global estimates that describe the prevalence of trichomonas as higher than that of chlamydia and gonorrhea combined. Table 49.1 lists epidemiologic risk factors for *T. vaginalis* infection in women.

Given the shared mechanism of transmission, it is not surprising that *T. vaginalis* infection often occurs with other STIs and reproductive tract infections (RTI) such as bacterial vaginosis (BV), and yeast (*Candida*) infection. Similar to prevalence rates, co-infection rates are available only as rough estimates as a result of limited data available that include testing for all organisms and due to the poor performance of microscopy for detection of trichomonas in women with other vaginal or cervical infections. Clue cells, epithelial cells with distinctive microscopic appearance that are indicative of BV, and lymphocytes that are a major component of discharge are both similar in size to trichomonads and may obscure motility. As a result, BV and yeast infections that are concurrent with trichomonal infections may hinder diagnosis of *T. vaginalis*. Women who are tested for STI, BV, or yeast infections should be evaluated for the presence of trichomonas and this evaluation may require more sensitive diagnostic methods than microscopy.

## HIV and Trichomonas

The relationship between HIV and discharge-causing STI is complex and bi-directional. Frequent co-infection of *T. vaginalis* with other STI and RTI and the shared mode of transmission add to the difficulty of understanding the exact effect of *T. vaginalis* on the risk of HIV acquisition and/or transmission.<sup>19</sup> Interestingly,

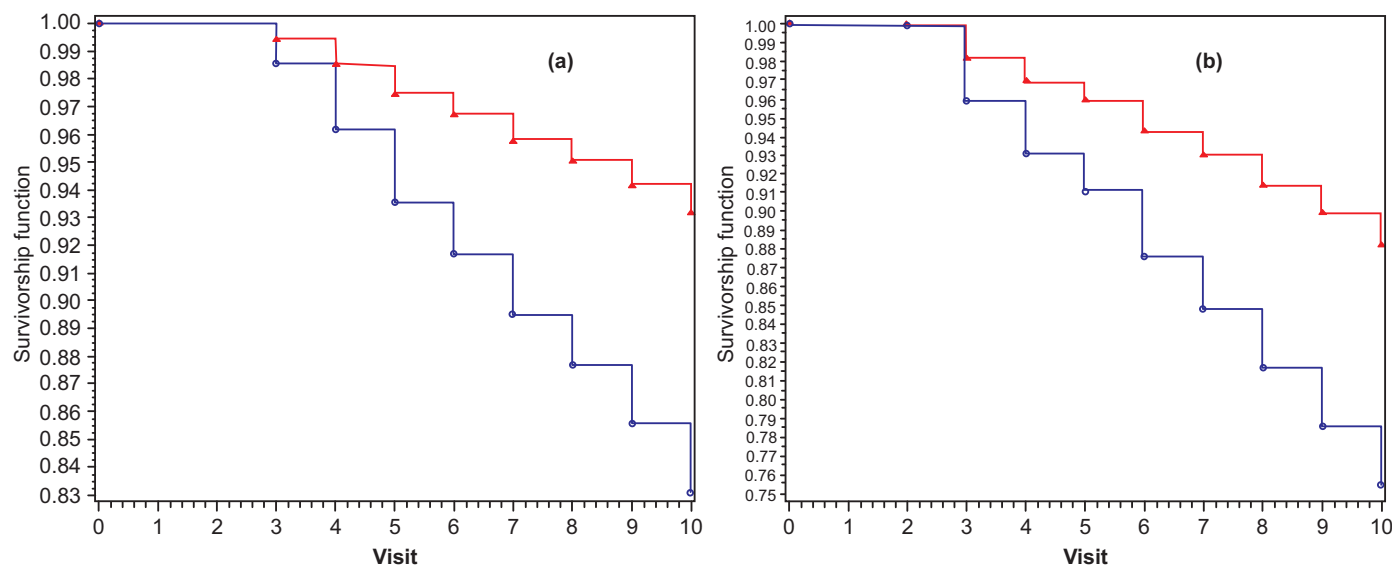

although little attention has been paid to trichomonal infection in men in the US, one of the first studies to identify a significant association between HIV and trichomonas was performed in men. Genital viral load has been shown to be one of the most important factors in predicting risk of HIV transmission within discordant couples. In men with symptomatic urethritis, *T. vaginalis* was significantly linked to increased concentrations of HIV in seminal plasma ( $p = 0.022$ ).<sup>20</sup> Men with trichomonas identified using DNA-based tests had six-fold increase in the concentration of HIV in semen compared to men without trichomonas. Similarly, in a prospective study of 203 HIV-positive women, treating *T. vaginalis* led to a 4.2-fold reduction in cell-free HIV viral load ( $p < 0.001$ ).<sup>21</sup> These results indicate seropositive men and women should be screened and treated for *T. vaginalis* infection in order to reduce HIV transmission to their sexual partners.

In a longitudinal study of women recruited from family planning clinics in Uganda and Zimbabwe, *T. vaginalis* was found to be more prevalent among HIV positive women than among matched controls (11.3% vs. 4.5%,  $p = 0.002$ ).<sup>22</sup> Moreover, HIV-negative women receiving a diagnosis of *T. vaginalis* were nearly 3 times more likely to become infected with HIV within the following 3 months than women without trichomonas (adjusted OR 2.74; 95% CI, 1.25–6.00). These data were from a general population of women and support the findings of other studies in populations consisting primarily of female sex workers.<sup>23,24</sup>

Mathematical modeling has derived similar risk estimates for HIV susceptibility and transmission.<sup>25</sup> The analysis estimated that *T. vaginalis* infection increases a woman's risk for HIV infection by 2–3 fold and is suspected to have had a huge impact on the HIV pandemic by increasing viral shedding in HIV-infected individuals and inflammation or micro-abrasions in genital tissues that enlarge HIV entry portals in HIV-negative partners (Fig. 49.3). Findings from the model of HIV transmission estimated the annual economic burden for trichomoniasis-attributable HIV cases to be \$167 million. This analysis demonstrates the interaction between high prevalence rates and a modest, but significant, increase in risk. While the effect on HIV risk of *T. vaginalis* infection cannot be altered, prevalence can, and must, be reduced by improved efforts to control this pathogen, particularly in populations at high risk for HIV infection.<sup>26,27</sup>

## Clinical Manifestations

Though often considered merely a nuisance, *T. vaginalis* infection in men is known to be an important cause of urethritis, prostatitis, and potentially male factor infertility.<sup>12,28</sup> Krieger et al. (1993) demonstrated an association between *T. vaginalis* and sexually transmitted non-gonococcal/non-chlamydial urethritis among a population of sexually active men.<sup>29</sup> Several studies have found *T. vaginalis* to be a common cause of urethritis in men.<sup>20,30–32</sup> Typical clinical practices do not include routine screening for trichomoniasis in men, even those who are symptomatic.<sup>33</sup> This is, in part, due to the limited sensitivity of tests that can be performed on-site.<sup>32</sup> The two most common diagnostic tests used

**Fig. 49.3:** Reciprocal effect of *T. vaginalis* and HIV. (a) Effect of trichomonas infection on HIV acquisition. (b) Effect of HIV status on risk of trichomonas infection. For women followed every 3 months for up to 3 years, Fig. 49.3 (a) shows the increase in risk over time of HIV acquisition for those women who have had a trichomonas infection (blue line) compared with those women who were never diagnosed with trichomonas (red line). Fig. 49.3 (b) shows the increase in risk of trichomonas infection following HIV acquisition (blue line) compared with those women who remained seronegative (red line) during the study period. More rapid decreases in the lines reflect rapid acquisition of disease. (Adapted from Napierella, et al. manuscript submitted.)

in clinical laboratory settings are wet mount microscopy and culture, and with such low sensitivities, these are poor diagnostic tools compared to DNA-based tests (see below).

Symptoms in men may include discharge, which may or may not contain significant quantities of lymphocytes or red blood cells, dysuria, pruritus, increased urinary frequency, or prostatitis. On rare occasions men may have urethral strictures or epididymitis. Symptoms generally appear within 7–10 days following exposure and it is possible that the infection may resolve spontaneously. Few longitudinal data are available to predict the frequency of such resolution. The vast majority of men with *T. vaginalis* may have no signs or symptoms of infection, thus confusing the measurement of natural clearance of disease. Diagnosis and treatment of these men remains clinically important in order to reduce the spread of the organism to sexual partners. Investigations performed more than 40 years ago reported infection in up to 45% of male partners of infected women and 100% of female partners of infected men.<sup>34</sup>

Asymptomatic carriers of trichomoniasis are an important reservoir of infection and diagnosis based solely on either the clinical signs or symptoms presented by the patient is unreliable.<sup>35</sup> Although *T. vaginalis* is commonly described in the context of non-gonococcal/non-chlamydial urethritis, trichomonas often occurs in men with chlamydia or gonorrhea. In one study, 23 of 37 men diagnosed with trichomoniasis and symptomatic urethritis had concomitant infection of gonorrhea.<sup>20</sup> Therefore, when screening for chlamydia and gonorrhea is appropriate, inclusion of screening for trichomonas should also be considered. With the development of nucleic acid-based diagnostics, this

testing can be performed on the urine samples being tested for chlamydia and gonorrhea.

Similar to men, women infected with *T. vaginalis* are also predominately without symptoms. While this has been well-documented over the last two decades, it is still common to encounter practitioners who believe that only symptomatic women should be tested. This misconception is supported by the fact that most testing is performed by wet preparation microscopy which is an insensitive test unless the number of organisms present is quite high. As a result, this test is most often positive in women with a high burden of organisms. High organism load leads to symptoms more often than a low burden. Thus the notion that all infected women have symptoms is a result of the poor sensitivity of the diagnostic test. Therefore, the utility of targeted diagnostics is questionable. When universal screening, rather than screening only symptomatic women, was evaluated in a women's correctional facility, the number of cases identified increased 4-fold.<sup>36</sup>

Women may experience vaginal discharge, vaginal itching, musty odor, dysuria, pelvic pain, irregular bleeding, and pain or bleeding on coitus. Clinical signs of infection in women include punctate bleeding of the cervix, often referred to as a "strawberry cervix" (Fig. 49.4), and a frothy discharge which is usually white but may be yellow or grayish in appearance. Vaginal pH greater than 4.5 may be noted in some women with trichomoniasis, but is not a highly reliable indicator.

In women, *T. vaginalis* infection has been linked to pelvic inflammatory disease (PID),<sup>37,38</sup> adverse outcomes of pregnancy,<sup>39–42</sup> and cervical cancer.<sup>16</sup> While the relationship between *T. vaginalis*

**Fig. 49.4:** Strawberry cervix. Typical appearance of the cervix of a woman infected with *T. vaginalis*. Punctate bleeding and micro abrasions are common features. Accessed from [http://bioweb.uwlax.edu/bio203/s2009/strous\\_mary/human\\_interaction.htm](http://bioweb.uwlax.edu/bio203/s2009/strous_mary/human_interaction.htm)

and PID in women with HIV has been shown to be strong (RR 1.9,  $p = 0.002$ ), in women without HIV the relationship was not significant ( $p = 0.4$ ).<sup>37</sup> The lack of a significant finding in HIV-negative women may have been due to a lack of power since the study sample included only 43 women. A study performed in the US did find an association between *T. vaginalis* and endometritis.<sup>38</sup> Additional studies using highly sensitive diagnostic techniques are needed to more clearly define the relationship between *T. vaginalis* and upper genital tract complications.

A prospective evaluation of the affect of *T. vaginalis* on pregnancy outcomes found significant associations between *T. vaginalis* and preterm delivery (before 37 weeks of gestation), low birth weight (infant weighing less than 2500 grams at birth).<sup>40</sup> Additionally, the likelihood of low birth weight was greater among Blacks (11%) than Hispanics (1.6%) or Whites (1.5%). These data emphasize the need for *T. vaginalis* control communities with high burden of disease and high likelihood of pregnancy complication.

## Diagnosis

### RAPID DIAGNOSTICS

*T. vaginalis* was first identified visually by microscopy of genital secretions by Donné in 1836.<sup>43</sup> Wet preparations, or wet mounts, are prepared by suspension of vaginal or urethral fluids in normal saline. The suspension is placed onto a slide and examined for motile trichomonads at 100 × magnification (low power) with confirmation of morphology using 400 × (high power). This technique remains the most frequently used diagnostic method even in technologically advanced settings. This test is simple, rapid, and inexpensive making it ideal for diagnosis in clinical settings. However, wet preparation microscopy is only 35–50% sensitive with higher sensitivity in women than men and in symptomatic individuals compared to asymptomatic patients.<sup>44,45</sup> This test is also hampered by rapid loss of motility at ambient temperatures and interference from other vaginal infections as mentioned above. However, despite the limitations of microscopy, this method was

found to be useful for identification of women with *T. vaginalis* in the context of HIV-control programs. In women attending family planning clinics in sub-Saharan Africa, a positive wet mount was associated with a nearly 4-fold increase in risk of HIV infection.<sup>22</sup> Therefore, microscopy, while not the best available diagnostic method, is preferable to no diagnostic evaluation in women at risk for HIV. In addition, microscopy offers the advantage of diagnosis during the office visit which increases the likelihood that patients will be treated for the infection.

Two commercially available assays with improved sensitivity can also be performed during an office visit. The OsomTrich (Genzyme Diagnostics, Cambridge, MA) dipstick assay provides results within 15 minutes and can detect twice as many infections as microscopy. The assay has excellent performance characteristics in low-<sup>46</sup> and high-prevalence populations.<sup>47</sup> An RNA probe assay, the Affirm (Becton Dickinson, Sparks, MD) test, can detect *T. vaginalis*, *Gardnerella vaginalis*, and *Candida* species in 45 minutes. This test performs better than microscopy and provides information that may lead to a diagnosis of yeast or BV as well as trichomoniasis, but requires specialized equipment and trained technicians.

### LABORATORY DIAGNOSTICS

Culture for detection of *T. vaginalis* was considered the gold standard of diagnosis until recently. Modified Diamonds Medium is enriched with yeast extract and supplemented with inactivated horse serum, amphotericin B, penicillin G, and gentamicin. This medium is formulated to allow trichomonads to grow, while suppressing bacterial growth. The addition of small amounts of agar reduces the oxygen tension, resulting in more prolific growth of trichomonads, which optimally grow and reproduce under anaerobic conditions.<sup>48</sup> Swabs containing vaginal secretions are inoculated into tubes containing medium and incubated for up to 5 days at 35–37°C. Each day a drop of the well-mixed culture fluid is placed on a slide and read microscopically in the same manner as a direct wet mount. Culture allows replication of the organisms thus increasing the probability of detection of motile organisms using microscopy. Culture will detect 1.5–3 times as many infections as direct wet mount microscopy in the clinic. An innovation in culture methodology is the InPouch culture system (BioMed Diagnostics, San Jose CA). This is a self-contained culture system that can be placed directly on to a microscope stage (Fig. 49.5). This allows microscopic evaluation of the entire culture rather than a single drop, thus improving the sensitivity.<sup>35,49,50</sup>

Currently, the most sensitive diagnostic methods for diagnosing trichomonal infections are nucleic acid amplification tests (NAATs).<sup>45,51–55</sup> These tests are based on enzymatic amplification of DNA or RNA to produce an exponential increase in the concentration of organism-specific targets. This amplification process increases the sensitivity of diagnostics to twice that of culture and 2.5–3.5 that of wet mount microscopy. NAATs are the most often used assays for screening for *C. trachomatis* and

**Fig. 49.5:** InPouch *T. vaginalis* culture system. Two culture pouches and the clip used to place these onto a microscope stage for direct examination of the entire culture. (Accessed from <http://www.biomeddiagnostics.com/images/InPouchTV.jpg>) In a longitudinal study of adolescent women,<sup>59</sup> 102 women provided vaginal swabs each week following diagnosis of trichomonas by NAAT. DNA-based testing was negative within 7 (95% CI 6, 9) days of treatment with metronidazole.

*N. gonorrhoeae*. Therefore, the opportunity to add trichomonas screening to samples collected for chlamydia and gonorrhea screening offers an advantage not previously available on a wide scale. While NAAT assays for *T. vaginalis* have been described that can be used in specialized research laboratories, fewer assays suitable for clinical labs were available.<sup>45</sup> Recently, a commercial assay has been made available for use on the Aptima system (Gen-Probe, San Diego, CA). While this assay is not FDA-approved at this time, it has excellent performance characteristics and is the only NAAT for detection of *T. vaginalis* RNA that is commercially manufactured.<sup>56</sup> Use of NAATs that can be performed on the samples collected for chlamydia and gonorrhea should encourage addition of trichomonas screening to routine sexual healthcare.

## Treatment

The recommended treatment for *T. vaginalis* infections is a single oral dose of 2 gram metronidazole (see review by Schwabke and Burgess).<sup>57</sup> Topical treatment has not been shown to be highly efficacious. The success rate of the oral regimen is approximately 85%. However, approximately 10% of failures are attributable to exposure to an untreated sexual partner. Therefore, management of sexual partners is strongly recommended. Metronidazole resistance has been reported in a small percentage of patients (<5%). Tinidazole, a compound related to metronidazole, is frequently used outside of the US to treat trichomoniasis (2 grams oral dose) with similar efficacy. This regimen may be useful for patients with metronidazole resistance infections. For a comprehensive review of clinical trials for treatment of trichomoniasis, see Forna and Gulmezoglu.<sup>58</sup> While treatment with these compounds is safe during pregnancy, there have been reports of a possible association between metronidazole treatment and preterm birth in women treated during the third trimester.<sup>57</sup>

Screening during the first trimester is recommended in order to minimize the possibility of adverse outcomes.

In a longitudinal study of adolescent women,<sup>59</sup> 102 women provided vaginal swabs each week following diagnosis of trichomonas by NAAT. DNA-based testing was negative within 7 (95% CI 6, 9) days of treatment with metronidazole. However, studies have shown high re-infection rates of trichomoniasis within a year following treatment, particularly in high-risk groups.<sup>13</sup> Therefore, women seeking care for symptoms more than 2 weeks after treatment should be evaluated for re-infection, particularly if their sexual partner(s) have not been treated. These data support the need for active partner management in any effort to control *T. vaginalis*, particularly in populations with high prevalence.

## Summary

- *T. vaginalis* is a sexually transmitted infection that is more prevalent than chlamydia and gonorrhea combined.
- Prevalence estimates are poor due to lack of public health monitoring of this pathogen.
- Women are 4–5 times as likely to be infected as men, but men carry and transmit the organism.
- Risks factors for trichomonas are similar to risks for other treatable STIs.
- *T. vaginalis* infection increases risk of acquiring HIV 2–4 fold and also increasing risk of transmitting HIV to sexual partners by increasing genital shedding of the virus.
- *T. vaginalis* infection has been implicated in increased risk of PID and cervical cancer and associated with preterm delivery.
- Infection with *T. vaginalis* is often asymptomatic and clinical algorithms designed to predict who should be tested are of limited utility.
- Diagnostic tests vary widely in sensitivity with wet mount performing worse than any other tests despite being the most commonly used method of detection. However, even the poorest test is preferable to not testing for *T. vaginalis*.
- NAAT diagnostics are the most sensitive assays available and can be bundled with chlamydia and gonorrhea screening with no additional effort on the part of the patient or clinician.
- Treatment with metronidazole is safe, inexpensive and efficacious particularly when coupled with treatment of infected sexual partners.

# Intestinal Protozoa

Lara Stabinski • Mahesh Sharma • Vineet Ahuja

50

## Introduction

Intestinal protozoa have gained importance during recent years as a result of increasing world travel, economic globalization, and a growing number of chronically immunosuppressed people. Overall, contamination of water and food with fecal matter is the most common route of transmission of intestinal parasites. However, several intestinal parasites, including protozoa, are now also widely recognized as sexually transmitted infections (STIs), especially in the population of men who have sex with men (MSM). A summary of gastrointestinal syndromes associated with intestinal protozoa and other sexually transmitted infectious agents is provided in Table 50.1.<sup>1–3</sup>

## Epidemiology of Intestinal Protozoa Associated with Sexual Transmission

In the late 1960s through 1980s, in the pre-AIDS era, a substantial increase in enteric pathogens and associated intestinal disease emerged in communities of gay men in several cities across the

US and Europe. Sexual transmission of these enteric pathogens through oral-anal intercourse was first recognized in 1967, in a case series of MSM in New York City experiencing intestinal protozoan infections.<sup>4</sup> Later, several other studies of MSM populations confirmed the sexual transmissibility of intestinal protozoa.<sup>5–10</sup>

*Entamoeba histolytica*, an amoeba, and *Giardia lamblia*, a flagellate, are the pathogenic protozoa most commonly associated with sexual transmissibility.<sup>11–13</sup> The amoeba *Blastocystis hominis*<sup>14,15</sup> and flagellate *Dientamoeba fragilis*,<sup>16,17</sup> whose pathogenicities are controversial can also be sexually transmitted. In addition, the coccidia *Cryptosporidia*<sup>18–20</sup> and *Microsporidia*,<sup>21</sup> important causes of diarrhea in immunosuppressed persons, have been associated with sexual transmission. There are also some case reports of sexual transmission of *Isospora*, another significant intestinal pathogen in immunosuppressed populations.<sup>22</sup> However, direct sexual transmission of *Isospora* and *Cyclospora* is improbable. Oocysts of these coccidian are excreted unsporulated and need to mature outside the human host to become infectious.<sup>23</sup>

**Table 50.1:** Sexually Transmissible Gastrointestinal Syndromes, Intestinal Protozoan and Non-Protozoan Etiologies

Syndrome	Signs and Symptoms	Intestinal Protozoa	Other Etiologies
Enteritis	Large volume, watery diarrhea, mid-abdominal cramps, nausea with or without vomiting, malaise, weight loss	<i>Giardia duodenalis</i> <i>Cryptosporidium</i> spp. <i>Microsporidium</i> spp.	<i>Strongyloides stercoralis</i>
Proctocolitis	Small-volume diarrhea, lower-abdominal pain, abdominal tenderness, anorectal bleeding, sensation of incomplete defecation	<i>Entamoeba histolytica</i> * <i>Cryptosporidium</i> spp.	<i>Shigella</i> spp. <i>Salmonella</i> spp. <i>Campylobacter</i> spp. Cytomegalovirus†
Distal Proctitis	<i>Acute:</i> Mucopurulent anal discharge, anorectal bleeding, constipation, sensation of rectal fullness or incomplete defecation <i>Mild or Chronic:</i> Mucus streaking of stool, constipation, occasional feeling of incomplete defecation	Protozoa uncommon	<i>Neisseria gonorrhea</i> <i>Chlamydia trachomatis</i> Genotype A-K Genotype L (LGV) <i>Treponema pallidum</i> Herpes simplex virus

\*Also a cause of liver abscess.

†In HIV seropositive patients (CD4+ T-cell count <100).

Many of the intestinal protozoa associated with sexual transmission in high-risk populations are considered commensal and are not generally associated with gastrointestinal disease.<sup>6,7,24</sup> These include intestinal amoebas *Entamoeba dispar*, *Entamoeba coli*, *Entamoeba hartmanni*, *Endolimax nana*, and *Iodamoeba butschii*, as well as flagellates *Chilomastix mesnili*, *Trichomonas hominis*, and *Retortamonas hominis*.

Although heterosexual transmission of enteric protozoa can occur, the prevalence of intestinal protozoa is much higher in MSM. In more recent studies, prevalence of infection with at least one protozoa varies from 49% to 57% in MSM and from 13% to 16% in control heterosexual populations.<sup>15,25–27</sup> Colonization with multiple protozoa in the MSM population is also much more prevalent. In a recent study of Australian MSM, more than 40% of them had multiple protozoa on stool examination in comparison to less than 10% in the non-MSM control group.<sup>15</sup>

However, prevalence rates of specific intestinal protozoa are difficult to ascertain as most stool surveys are done in high-risk populations such as patients of STI clinics or in symptomatic

patients. In addition, stool studies are often done using one stool sample per participant, and therefore may underestimate the prevalence of intestinal protozoa.<sup>28</sup> Moreover, pathogenic *E. histolytica* is morphologically difficult to distinguish from nonpathogenic *E. dispar* and these are often reported as one category. The prevalence of common enteric protozoa in selected high- and lower-risk groups, as reported in some published studies, are shown in Table 50.2.<sup>6,15,24,25,27,29–35</sup>

Initially, the post-AIDS era, safer sex practices in reaction to the AIDS epidemic, led to a decrease in STIs including both symptomatic and asymptomatic enteric protozoan infections in MSM populations. However, the availability of highly active antiretroviral treatment (HAART) has led to a degree of sexual disinhibition associated with an increase in STIs in this population including intestinal protozoa in some populations.<sup>36</sup> Recently, pathogenic infections with *E. histolytica* re-emerged as potentially significant causes of intestinal disease in MSM and HIV-positive persons in the Australia and the Asia Pacific region including Japan, Taiwan, and the Republic of Korea.<sup>37–41</sup>

Adapted from Abdolrasouli A, et al. Sexual transmission of intestinal parasites in men who have sex with men. *Sex Health* 2009;6:185–94.

\*Year published.

†Rounded to nearest 1%.

‡Known HIV men excluded, 62% tested.

MSM indicates men who have sex with men.

As most of the protozoan infections in MSM are not associated with symptoms, many remain undiagnosed.<sup>6,7,24</sup> However, despite the high prevalence of asymptomatic infections, a better understanding among clinicians of sexually transmitted intestinal protozoan infections in this population is important. Even those with symptoms, often do not undergo proper evaluation for intestinal protozoa, especially in the absence of a travel history, as many clinicians are not aware of the risk of sexual transmission of intestinal parasites in this population. In addition, colonization with commensal protozoan organisms is often an indication of presence of other pathogenic protozoa in this population.<sup>8,31</sup> In the presence of symptoms, patients with a stool sample positive for commensal organisms should have evaluations of additional stool samples for pathogenic protozoa. Moreover, the higher prevalence of HIV in this risk group, in combination with the high underlying prevalence of protozoan infection, increases the risk of serious gastrointestinal infections in the immunosuppressed within this risk group.

## Sexual Risk Factors and Transmission

Oral-anal sex, also known as anilingus, is a sexual practice involving contact between the anus or perineum of one person and the mouth, lips, or tongue of another. Non-clinical, vernacular terms include rimming, rim-job, and salad tossing. It can be performed by people of all sexual orientations, and is a common practice in MSM.

Anilingus facilitates fecal-oral transmission of enteric pathogens and commensal organisms.<sup>10,42</sup> It is also the most significant independent risk factor associated with the transmission of *G. lamblia* and *E. histolytica* in the MSM population.<sup>6,7,31,34,43</sup> Frequency of anilingus and lack of anal cleaning before anal sex also have been correlated with protozoan infection.<sup>7,34</sup> Other risk factors for transmission of protozoa include number of sexual partners and history of other STIs, including syphilis and gonorrhea.<sup>34,44</sup> Some experts have argued that protozoan infections are less prevalent among heterosexuals because protozoan infection is not endemic in this group, and that there is less chance of exposure given generally fewer sexual partners and less frequent anilingus in this group.<sup>6</sup>

Among MSM, other than anilingus, other possible routes of sexual transmission of protozoan are oral-penile sex involving a fecally contaminated penis, intra-rectal transmission through the insertion of a contaminated penis into a rectum, digital-anal contact, fisting, and coprophagia.<sup>6,7,45</sup> Sharing sex toys and colonic cleansing equipment have also been implicated in transmission of protozoan infections.<sup>46</sup>

## Sexually Transmissible Protozoan Infections

Those intestinal protozoa excreted in the feces with the lowest infectious dose are most likely to be transmitted sexually. *E. histolytica* and *Giardia lamblia* both have a very low infectious dose (10–100 cysts) and are the most common and clinically significant sexually transmissible protozoan infections. *Cryptosporidium* also has a very low infectious dose (130 oocysts) and is sexually

transmissible. It is an important cause of intestinal disease and diarrhea in immunosuppressed persons, especially in MSM with advanced HIV infection. *Microsporidia* causes similar symptoms in immunosuppressed persons and can also be transmitted sexually, but is much less common, especially in the post-HAART era.

With the exception of *B. hominis* and *D. fragilis*, which have occasionally been associated with diarrheal disease in humans, other sexually transmitted protozoa are generally considered commensal and are not generally associated with intestinal disease in humans.

## ENTAMOEBA HISTOLYTICA

Amebiasis is an infection of the human gastrointestinal tract caused by *E. histolytica*. The parasite is capable of invading the intestinal mucosa and may spread to other organs, principally the liver, where it results in liver abscesses. *E. dispar* and *Entamoeba moshkovskii*, which are morphologically identical to *E. histolytica*, also colonize the human gut. *E. dispar* is now recognized as a species with no infective potential.<sup>47–50</sup> *E. moshkovskii*, was recently found to colonize 2% of MSM screened in a large study in Australia.<sup>15</sup> However, its role as a pathogenic organism is still being elucidated. In one study, *E. moshkovskii* was recognized as the only organism found in more than 5% of persons with diarrhea and abdominal pain.<sup>51</sup>

## Biology

*E. histolytica* exists in either trophozoite or cyst form.

### Trophozoite

The trophozoite is the motile form of *Entamoeba*. It is strongly affected by changes in temperature, pH, osmolarity, and redox potential. Actively motile amoebae are elongated, whereas resting trophozoites tend to be spherical (Fig. 50.1). The cell surface has

**Fig. 50.1:** *Entamoeba histolytica* trophozoite. Trophozoites vary in size from 12–60 microns. There is a single round nucleus, with a central dot or karyosome and an even distribution of chromatin around the nucleus. Ingested erythrocytes may be seen in the cytoplasm. (From Collection of Dr. John Keiser, George Washington University, 2009).

numerous openings that correspond to micropinocytic vesicles. The plasma membrane is covered by a uniform surface coat composed of glycoproteins. The cytoplasm of the trophozoite is characterized by the absence of mitochondria, golgi apparatus, rough endoplasmic reticulum, centrioles, and microtubules. The cytoplasm contains abundant vacuoles.<sup>52</sup>

### Cyst

*E. histolytica* cysts are round or oval hyaline bodies, surrounded by a retractile wall composed of fibrillar material. The plasma membrane has deep invaginations: polyribosomes and vacuoles containing dense fibrogranular material. Staining with iron hematoxylin makes the cytoplasm appear vacuolated with numerous glycogen deposits that decrease in size and number as the cyst matures. Iodine stains allow the clear visualization of one to four small nuclei.<sup>53</sup>

*E. histolytica*, *E. dispar*, and the more recently identified, *moshkovskii*, are morphologically identical. The existence of a species complex was first suggested in studies in which zymodemes (patterns of electrophoretic mobility of certain parasitic isoenzymes) were analyzed. Distinctive zymodemes were associated with symptomatic invasive disease or with asymptomatic carrier state. Further research with RNA and DNA probes clearly indicated two separate species: *E. histolytica* and *E. dispar*. Numerous antigenic differences between the two species have been demonstrated. Distinct epitopes present on the 170-kDa heavy subunit of the galactose inhibitable adherence lectin, which is a highly conserved antigen, are found in *E. histolytica* but not in *E. dispar*. Monoclonal antibody probes, and more recently, polymerase chain reaction (PCR), have been used to differentiate between the *Entamoeba*.

Morphologically, the presence of ingested erythrocytes is associated with the presence of *E. histolytica* and not of *E. dispar*, but these are often difficult to appreciate.<sup>54</sup>

### Life Cycle

Infection is acquired by ingestion of the cyst form that is resistant to the acidic pH of the stomach. Excystation occurs in the small bowel, with division of mature quadrinucleated cyst into four and then eight trophozoites by nuclear and cytoplasmic division. The trophozoites move into and colonize large bowel feeding on bacteria and cellular debris. If luminal conditions are less ideal, the trophozoites can encyst. The cysts are then excreted and may remain viable for weeks or months. Infection is not transmitted by trophozoites, which may be excreted during episodes of acute colitis, because of their rapid degeneration in environmental conditions. Infection may result from ingestion of cyst in contaminated food or water, or through oro-anogenital contact, as discussed above.

### Epidemiology

The main reservoirs of *E. histolytica* are humans. It is estimated that 10% of the world's population is infected by *E. dispar* or *E.*

*histolytica*. *E. dispar* infection is at least 10-fold more common than *E. histolytica* infection. Symptomatic invasive amebiasis develops only in 10% of individuals with *E. histolytica* infection. Therefore, disease will develop in only 1 of 100 individuals who are determined to be asymptomatically infected with *E. histolytica/dispar* by stool microscopy.

High rates of amoebic infection are seen in the Indian subcontinent, Southern and Western Africa, the Far East, and in South and Central America.<sup>55,56</sup> A high prevalence of *E. histolytica* was also shown in early studies of MSM (Table 50.2), but these studies did not differentiate between *E. dispar* and *E. histolytica* because of their morphologic similarity. Data from more recent studies indicates that most of these infections were likely due to *E. dispar*.<sup>15,25</sup>

Asymptomatic *E. histolytica* infection results in a humoral immune response and consequent production of serum antibodies, while *E. dispar* infection does not lead to a positive serology. There is a clear correlation between high seroprevalence and low socioeconomic and educational levels and inadequate housing conditions. Patients not at increased risk of infection but among whom the mortality due to invasive amebiasis is high include malnourished individuals, children younger than 1 year of age, pregnant women, and individuals receiving steroid therapy.

Recently, *E. histolytica* infection has also re-emerged as a significant cause of intestinal disease and liver abscess in MSM and persons with HIV in the Asia Pacific region.<sup>37,39,40,57,58</sup> It is unclear if HIV-related immunosuppression is associated with more serious infections with *E. histolytica*, as many previous studies have been contradictory and have had limitations. However, recent data suggest that HIV-infected persons may be at increased risk of invasive amebiasis.<sup>40,59</sup>

### Pathogenesis

The powerful lytic activity of *E. histolytica*, for which the parasite was named, has inspired a variety of approaches aimed at understanding the pathogenesis of invasive amebiasis. Intestinal invasive amebiasis can lead to amoebic ulcerative colitis, toxic megacolon, amoeboma or colonic granuloma, and amoebic appendicitis.

In invasive disease, intestinal ulcers may be found in the cecum, sigmoid colon, and rectum. These ulcers are characteristically shallow with broad elevated margins and are filled with fibrin.<sup>60</sup> The late invasive lesion presents with deep ulceration and a flask-like appearance.

This mucosal ulcer extends deep into a larger area of the submucosa, which seems to be particularly susceptible to the lytic action of the parasite. There is a rapid lysis of inflammatory cells around the invading amoebae, thus acute inflammatory cells are seldom found in biopsy samples or in scrapings of rectal mucosal lesions.

### Immunology

The time between infection with *E. histolytica* and appearance of local antibody responses remain unknown. High titers of antibodies tend to appear early in the disease and persist after

invasive or subclinical amebiasis is cured or controlled. The detection of antibodies depends on the sensitivity of the test used. If antibodies are measured by sensitive techniques of indirect hemagglutination test or by enzyme-linked immunosorbent assays (ELISA), they can be detected for more than 3 years after an invasive amoebic episode in the absence of recurrent infection.

Although a rapid humoral immune response is mounted by the host upon invasion by *E. histolytica*, the parasite has developed efficient evasion mechanisms that include resistance to complement and a mechanism for capping and shedding of surface antigens. It is therefore thought that humoral antibodies are not protective against *E. histolytica*. This conclusion is supported by the observation of a high rate of re-infection in persons with elevated antibody titers.

## Clinical Features

The term amebiasis includes all cases of human infection with *E. histolytica*. However, only a proportion of cyst-releasing individuals experience symptoms. Symptoms are caused by the penetration of the parasite into the tissues. This disease process is known as invasive amebiasis.

### Intestinal Amebiasis

Patients with acute amoebic colitis present with a 1- to 2-week history of abdominal pain, tenesmus, and frequent loose, watery stools containing blood and mucus. Despite the presence of mucosal ulcerations and occult blood in stools, fecal leukocytes may not be found because of the lytic activity of the parasite. Endoscopy may show the characteristic appearance of the punctate, hemorrhagic ulcers dispersed throughout a normal appearing mucosa.

Fulminant colitis is an unusual complication of amoebic dysentery and is associated with a grave prognosis. Patients with fulminant colitis present with severe bloody diarrhea, fever, and diffuse abdominal tenderness of rapid onset. The fulminant disease often progresses so rapidly that only 25% of adults with colonic perforation evident at laparotomy present with a rigid abdomen.

An amoeboma, or an amoebic granuloma, of the colon may present with a mass-like lesion in the right iliac fossa. Other less frequent complications of amoebic colitis include gastrointestinal hemorrhage, amoebic appendicitis, and amoebic strictures of the anus, rectum, or sigmoid colon.

### Extraintestinal Amebiasis

Amoebic liver abscess is the most common form of extraintestinal amebiasis. Patients typically present with fever and right upper-quadrant abdominal pain. Most patients have tender hepatomegaly. Jaundice is an unusual finding. Atypical features include shortness of breath and cough secondary to pleural effusion or rupture of the abscess into the pleural space. Less than 30% of patients have had active diarrhea at any time before presentation, even though

intestinal infection by *E. histolytica* must have occurred. Rupture of an amoebic liver abscess into the peritoneum occurs in 2% to 7% of cases; left-lobe abscesses are more likely to rupture because of their delayed clinical presentation. Brain abscess, and rarely, genitourinary disease, can also occur.<sup>61,62</sup>

## Diagnosis

Diagnosis of invasive intestinal amebiasis is traditionally made by demonstration of *E. histolytica* parasite in the stool. *E. histolytica* cysts may remain viable for some time in unpreserved stools, while trophozoites are labile and remain in stool for about 30 minutes. The diagnostic yield is better if the specimen is collected every day for a period of 3 days or longer. For examination of stool specimen, an iodine-stained smear as well as a concentration test should be done.

However, it is difficult to distinguish *E. histolytica* from *E. dispar* morphologically. Ingested red blood cells (hematophagous trophozoites) are indicative of *E. histolytica*, but this is an uncommon finding and can't be relied upon for diagnosis. Charcot-Leyden crystals are associated with amebiasis but are not specific for it. Confirmation with enzyme immunoassays or PCR is necessary.<sup>63</sup> PCR is more sensitive (80–100%) and more specific (85–100%) than microscopy, but is costly. Enzyme immunoassays are specific (100%) but are less sensitive than PCR.<sup>64</sup>

Serum antibodies to amoebae develop in response to *E. histolytica* infection but not to *E. dispar* infection. The absence of serum antibodies to *E. histolytica* after 1 week of symptoms is strong evidence against the diagnosis of invasive amebiasis of the colon or liver. Serum antibodies to amoebae are detected in 85% to 95% of all patients who present with invasive amebiasis or liver abscess. However, as antibodies persist for many years, ELISA or indirect hemagglutination cannot differentiate acute from remote infection in areas of high endemicity. Ultrasound is very useful for diagnosis of amoebic liver abscess. The classic appearance is of a nonhomogeneous hypoechoic round or oval mass with well-defined borders. Complete resolution of an amoebic liver abscess may take up to 2 years.<sup>65</sup> Percutaneous diagnostic needle aspiration is needed to differentiate between amoebic and pyogenic liver abscesses.

Newer diagnostic strategies involve detection of protein antigens in feces or serum by monoclonal antibodies and detection of parasitic DNA by use of nucleotide probes and PCR amplification. A commercial ELISA kit that uses monoclonal antibodies directed against an amoebic adherence lectin and accurately differentiates the true pathogen, *E. histolytica* from *E. dispar*, has recently been developed for clinical use.<sup>66,67</sup> Detection of amoebic lectin antigen in serum samples from patients with amoebic liver abscess is more than 95% sensitive if used prior to treatment with metronidazole.

## Management

Metronidazole 800 mg administered orally three times daily for 5–8 days is preferred treatment for invasive disease. Alternately, a single dose of Tinidazole 2 g can be used. Diloxanide furoate

500 mg three times daily for 10 days should be administered concurrently to decolonize the gut. Sexual partners within the preceding 3–4 months should be assessed for infection. Stool samples should be examined at monthly intervals for 3 months after treatment and should remain negative.<sup>1</sup>

## GIARDIASIS

*G. lamblia* is an intestinal flagellate that infects both humans and animals, and is the most common cause of intestinal parasitic disease in humans worldwide. It is also known as *G. intestinalis* or *G. duodenalis*.

## Biology

*Giardia* possesses both trophozoite and cyst forms. The trophozoite is ‘sting ray’ shaped. The organism’s two nuclei and central parabasal bodies give it the appearance of a face with two bespectacled eyes and a crooked mouth (Fig. 50.2). There are four pairs of flagellae: anterior, lateral, ventral, and posterior. These parasites reside in the alkaline environment of duodenum and jejunum. They move about the unstirred mucous layer at the base of the microvilli with a tumbling or “falling leaf” motility. With the aid of a large ventral sucker, they attach themselves to the brush border of the intestinal epithelium. In the descending colon, the flagellae are retracted into the cytoplasmic sheaths and a cyst wall is secreted. These forms are oval in shape. The internal structures divide producing a quadrinucleate organism. The mature infective cyst forms can survive in extreme conditions.

## Epidemiology

Giardiasis has a cosmopolitan distribution. It has the highest prevalence in urban areas with poor sanitation. In developing countries, infection rates may reach 25% to 30%. But even in

**Fig. 50.2:** *Giardia lamblia* trophozoite. Trophozoites are 9–12 microns long and 5–15 microns wide. They are characterized by 2 nuclei with large central karyosomes, two parabasal bodies below the nuclei, a large ventral sucking disk for intestinal attachment, and the presence of flagella. (From Collection of Dr. John Keiser, George Washington University, 2009).

developed countries, it is the most frequently identified intestinal parasite. Young children and young adults are most frequently infected. Children with luminal immunoglobulin A deficiencies are most susceptible to *Giardia* infection.

Infection usually follows ingestion of viable cysts of the parasite in contaminated food or water. Fecal-oral transmission of *Giardia* among MSM is also well documented and prevalence rates in this population vary from 2% to 13% in most studies (Table 50.2). Disease in this population is associated with 50% of infected cases. *Giardia* has been associated with HIV, and in some studies has been linked with more severe disease in this population.

## Life Cycle

As few as 10–25 cysts may establish infection. Excystation is initiated by contact with acidic gastric juice followed by release of one or two trophozoites. The trophozoite (Fig. 50.2) infects the duodenum and upper intestine and gives rise to clinical sequelae. As trophozoites pass through the small intestine to the colon, encystation occurs.<sup>68,69</sup>

## Pathogenesis

The sequence of pathogenic events is ingestion, then colonization followed by adhesion. The mechanisms of parasite adherence include (i) mechanical adhesion related to ventral flagella and ventral sucker disc, and (ii) lectin-mediated, mannose-dependent adhesion.

Giardiasis produces absorptive defects associated with parasite-induced damage at the microvillous border. The microvillous damage is usually proportional to the parasite density. Parasite movement on the surface of small intestine may lead to interruption of lectin adhesion to the enterocytes, disordering of enzymes and surface membranes of microvilli, and the accumulation of osmotically active particles of unabsorbed nutrients in the lumen leading to diarrhea. Active uptake of bile salt concentrations by trophozoites also alters micelle formation causing malabsorption of fats. In addition, *Giardia* can interfere with the function of pancreatic lipase *in vitro*, and small bowel bacterial overgrowth can occur.<sup>70–73</sup>

## Pathology

Morphological changes can occur in the jejunum and the duodenum and are associated with more severe disease. Villi are often shortened and crypts are elongated. Intraepithelial lymphocytes are increased in number. Lamina propria infiltrate with plasma cells and lymphocytes may also be seen. *Giardia* trophozoites may be visualized in the intervillous spaces and on the microvillous border of the epithelial cells.

## Clinical Features

The majority of individuals infected with *Giardia* are asymptomatic. Typical clinical symptoms begin 1 to 3 weeks after ingestion of cysts and are marked by diarrhea, malaise,

flatulence, greasy stools, and abdominal cramps. Diarrhea is often explosive in nature and is foul smelling. Vomiting and fever are less common and blood- or mucus-tinged feces are rare. Individuals can also develop subacute and chronic infections. In patients with chronic giardiasis, diarrhea can lead to dehydration and malabsorption. Children may develop growth retardation. Healthy patients with domestically acquired giardiasis from sexual or other close personal contact commonly present with gas and cramps but no frank diarrhea.

## Diagnosis

Laboratory diagnosis of *Giardia* infection is made by examination of fresh stool samples for cysts and trophozoites. At least three stool samples should be examined before a negative result is reported.

If stool tests are negative, jejunal biopsy can be helpful in making a diagnosis. In addition, many commercial antigen tests are available. These tests are more sensitive (90–100%) than microscopy. PCR can also be used to diagnose *Giardia*.<sup>74,75</sup>

## Management

Preferred therapy for *Giardia* includes metronidazole 2 g orally as a single dose daily for 3 days or metronidazole 400 mg orally three times per day for 5 days. Alternately, Tinidazole 2 g orally as a single dose may be used. All sexual partners within the preceding month should be assessed for symptomatic infection. Three negative consecutive stool samples taken at least 24 hours apart should be evaluated to confirm cure.<sup>1,76–79</sup>

## CRYPTOSPORIDIOSIS

The *Cryptosporidium* species are intracellular protozoan parasites that have emerged as an important cause of diarrhea among humans. Of the 10 species of *Cryptosporidium*, only *C. parvum* is widespread in humans and other mammals. This parasite has received a great deal of attention in the past several years because of the persistent and profuse diarrhea and morbidity it causes in immunocompromised patients, most notably in those with the acquired immunodeficiency syndrome (AIDS). It is also associated with community water-borne outbreaks of diarrhea in otherwise healthy individuals.<sup>80,81</sup>

## Life Cycle

*C. parvum* is an *apicomplexan* protozoal parasite. *Cryptosporidium* exists in the environment as a 5- $\mu$ m oocyst (Fig. 50.3), which contains four sporozoites. Humans and animals are infected by ingesting these oocysts, which travel through the gut lumen to the small intestine where they rupture, releasing the sporozoites. Sporozoites are infective and attach to epithelial cells, after which they become enveloped by the host apical cell membrane and differentiate into the spherical trophozoites. *C. parvum* resides intracellularly but outside of

**Fig. 50.3:** Acid-fast *Cryptosporidium* oocysts, usually approximately 5–7  $\mu$ m in diameter. (From collection of Dr. John Keiser, George Washington University, 2009).

the cytoplasm, in contrast to the other intracellular pathogens (e.g., *Toxoplasma*) that are located in parasitophorous vacuoles within the cytoplasm.

## Immunology

The mechanism by which *Cryptosporidium*-infected intestinal epithelial cells initiate immune response is not entirely clear. One apparent mechanism in human cells involves the production of tumor necrosis factor alpha, interleukin-8, and C-X-C chemokines by infected mucosa.<sup>82,83</sup>

## Epidemiology

Human infection with *Cryptosporidium* has been reported in more than 90 countries and 6 continents. Specific groups at greater risk of infection include children, malnourished persons, and immunocompromised individuals including AIDS patients, transplant recipients, and persons receiving chemotherapy.

The oocyst is the form transmitted from an infected host to a susceptible host by the fecal-oral route. Routes of transmission can be (i) person to person, (ii) animal to animal, (iii) animal to human, (iv) water-borne, (v) food-borne, and (vi) possibly air-borne.<sup>84–89</sup> Oocysts of *C. parvum* can remain viable for many months. *Cryptosporidium* has been recognized as the most common parasite associated with chronic diarrhea among MSM with HIV-related immunodeficiency and is associated with a prevalence of up to 33% in some HIV-positive MSM populations in the pre-HAART era.<sup>90</sup>

## Pathogenesis

Both the processes of intestinal absorption and secretion are regulated by intestinal epithelial cells infected by *Cryptosporidium*. In experimental models of cryptosporidiosis, impaired glucose-stimulated sodium and water absorption and/or increased chloride secretion have been identified as pathogenic mechanisms. Abnormalities in the barrier

properties of the intestinal epithelium, mediated in part by intercellular junctional complexes also contribute to *Cryptosporidium* diarrhea. In addition, investigations have found evidence of permeability defects and decreased resistance across *C. parvum*-infected intestinal cell lines.

## Clinical Features

Although asymptomatic infection is well documented, more than half of infected persons develop chronic disease and about 10% develop fulminant disease. The incubation period of *Cryptosporidium* infection ranges from 2 to 14 days. The manifestations include watery and profuse diarrhea with abdominal cramps, nausea, vomiting, and low-grade fever. In immunocompetent individuals, the disease is usually self limited.

In contrast, the duration of illness is prolonged in the immunocompromised host and the symptoms are generally more severe. In addition to diarrhea, malabsorption can result secondary to decreased absorptive surface. This contributes to the wasting syndrome seen in HIV-infected persons with advanced immunosuppression. Immunocompromised patients who develop biliary infection can also present with acute cholangitis.

*Cryptosporidium* infection can also lead to chronic malnutrition in previously normal children. This may be due to persistent malabsorption secondary to *C. parvum*-induced intestinal injury or enhanced susceptibility to other pathogens.<sup>91</sup>

## Diagnosis

A variety of diagnostic options are available for the detection of *Cryptosporidium* in stool samples. The diagnosis depends on the identification of the 5- $\mu$ m spherical oocysts in stool or the intracellular stages within biopsy specimens of gastrointestinal mucosa. Duodenum is a reasonable site for biopsy in AIDS patients infected with cryptosporidiosis.<sup>92</sup>

Conventional detection methods include stool concentration and staining of fecal smears. Auramine-rhodamine screening of stool sediment smears followed by acid-fast (Ziehl-Neelsen) staining is a sensitive and specific approach for the diagnosis. Cryptosporidial oocysts should be discriminated from *Cyclospora* oocysts which are significantly larger (10  $\mu$ m).

Immunological-based techniques including polyclonal fluorescent antibody tests, latex agglutination reactions, immunofluorescence with monoclonal antibodies, ELISA, and solid-phase qualitative immunochromatographic assays have been developed for the detection of cryptosporidiosis.<sup>93,94</sup> These tests may also show some cross-reactivity to non-*C. parvum* oocysts.

A variety of PCR tests offer alternatives to conventional diagnosis of *C. parvum* for both clinical and environmental specimens. Although PCR is rapid, highly sensitive, and accurate, it has several limitations. False-positives can result from detection of naked nucleic acids, nonviable microorganisms, and laboratory contamination. The PCR can also be inhibited by some stool components. An advantage of PCR is that genetic information obtained from the sample may permit nonhuman pathogens to be distinguished from human pathogens.<sup>95–98</sup>

## Summary

Common Sexually Transmitted Protozoa, Major Clinical Syndromes, Diagnosis and Management

Organism	Major Clinical Presentation	Diagnosis	Management
<i>Entamoeba histolytica</i>	Amebiasis Intestinal proctocolitis Liver abscess	Stool for ova and parasites, serology, fecal antigen testing, Ultrasound, serologic tests	<i>Treatment</i> Metronidazole or tinidazole plus diloxanide furoate to decolonize the gut <i>Follow-up stool samples</i> Should be examined at monthly intervals for 3 months after treatment <i>Testing of Partners</i> Partners within the proceeding 3–4 months should be assessed for infection
<i>Giardia lamblia</i> (intestinalis)	Malabsorption and noninflammatory diarrhea	Stool for ova and parasites, fecal antigen testing	<i>Treatment</i> Metronidazole or Tinidazole <i>Follow up stool samples</i> Three consecutive stool samples 24 hours apart to confirm cure <i>Testing of Partners</i> Partners within preceding month should be evaluated
<i>Cryptosporidium parvum</i>	Noninflammatory diarrhea, usually self-limiting Severe diarrhea and cholangitis in HIV-related immunosuppression	Acid-fast staining of stool samples, small bowel biopsy	<i>Treatment</i> Immune reconstitution, supportive care, nitazoxanide <i>Follow-up stool samples</i> Not necessary in immunocompetent patients <i>Testing of partners</i> Not recommended under current guidelines

## Management

Unfortunately, there is no completely effective treatment for *Cryptosporidium*. Cellular immunity is critical in clearing the pathogen. In immunocompromised hosts, cryptosporidiosis can be life-threatening, particularly if CD4<sup>+</sup> cell count is below 200/ $\mu$ L. In this case, ideal treatment involves restoring of immune function with HAART.<sup>99</sup> Another agent that may have some benefit in severe infections is nitazoxanide taken 500 mg twice daily. Recommended duration of therapy is 3 days for immunocompetent persons and 14 days for those with HIV-related immunosuppression.<sup>100–102</sup>

In immunocompetent patients, infection is self-limited with duration of 2–26 days. Treatment consists of adequate hydration with or without antimotility agents to control symptoms. Sexual partner notification and assessment is not recommended in the current guidelines. Follow-up stool samples in immunocompetent patients are not necessary.

## Scabies

Human scabies is an ectoparasitic infestation caused by the itch mite *Sarcoptes scabiei* var *hominis*. It is the first human disease for which an infectious agent was identified as the cause.<sup>1</sup> The disease has assumed pandemic proportions and in the present scenario of human immunodeficiency virus (HIV) infection, scabies has become more rampant with atypical presentations.

Although scabies is frequently described as a sexually transmitted infection, opinions differ on the appropriateness of this description. Some authors reported sexual transmission in 60–80% of patients with scabies. In 1946, Heilesen reported sexual transmission in 62% of the 231 patients he had treated.<sup>2</sup> Felman et al.<sup>3</sup> suggested that sexual transmission is the primary mode of spread in adults and reported that 60–80% of cases of scabies were acquired by sexual contact or sleeping together in the same bed. In studies in the United States Navy, most cases were believed to be acquired by sexual contact.<sup>4</sup> Some authors suggested that the increase in scabies in the 1970s was due partly to increased promiscuity and that it ran parallel to the increase in incidence of head and pubic lice.<sup>4,5</sup>

In contrast to these views, it has been stressed that transmission of the mites requires close body contact but not necessarily sexual contact, unlike sexually transmitted infections such as syphilis. Further, scabies does not fit in the classic patterns of a sexually transmitted infection. Trends in the incidence of scabies do not parallel those of common sexually transmitted infections. Gordon et al.<sup>6</sup> suggested that it should more appropriately be called a “family disease.”

It is true that scabies, as a sexually transmitted infection, has not been widely studied but venereologists often attach significance to this condition, as it could be an indicator to look for the presence of other sexually transmitted infections. Whatever be the mode of transmission, the clinical presentation of scabies does not vary much. Scabies has been a common disease for at least 3000 years. The word scabies is believed to be derived from the Latin term *Scabere*, meaning “to scratch” and possibly from the “scabs” of secondary bacterial infection.<sup>7</sup> The disease is

known by various names like acariasis, 7-year itch, camp itch, and Norwegian itch. In mammals, the condition is known as sarcoptic mange, and in birds as scaly leg. The itch mite was known for centuries before it was accepted by the medical world as the causative agent of scabies. Avenzoar and his student Averroes in Spain first described the scabies mite in the 12th century, although they did not link it with the associated skin eruption.<sup>1</sup> August Hauptmann is believed to be the first person to show the mite in 1654. Giovanni Bonomo, in a letter to Fransesco Redi, described and drew the scabies mite in 1687.<sup>8</sup> von Hebra showed in 1844 that scabies was a local and not an internal disease. Thomas Hillier in 1865 wrote in his “Textbook of Skin Diseases” that the mite *Sarcoptes hominis* was the cause of scabies. It has thus been described as the first disease in humans with a known cause.<sup>1</sup> In 1943, Mellanby described the life cycle of the mite.

## BIOLOGY

The *Sarcoptes scabiei* belongs to the phylum Arthropoda, class Arachnida, order Acariformes, suborder Astigmata and family Sarcoptidae.<sup>9</sup> Mites of dogs, horses, and other animals are morphologically indistinguishable from *S. scabiei* var *hominis*, but are physiologically different and host specific.

## MORPHOLOGY

The adult female mite is ovoid in shape with a translucent white color, 330–450  $\mu\text{m}$  long and 250–350  $\mu\text{m}$  wide (Fig. 51.1). There are four pairs of legs. The anterior two pairs end in suckers and the posterior two pairs end in bristles (Fig. 51.2). The adult male mite is roughly half the size of the female. The main difference is the presence of sucker on the fourth leg (Fig. 51.3), which is a bristle in the female.<sup>10</sup>

## LIFE CYCLE

The female, once impregnated, is fertile for the rest of its life. Ovigerous female is the most important infective form. A single fertilized female can initiate and perpetuate the infection. It selects

Fig. 51.1: Adult female mite.

Fig. 51.2: Dorsal surface of adult female.

places on the body where the skin is thin and wrinkled. The mite walks on the surface of the skin at a speed of about 2.5 cm/min. Burrows are created at the base of the stratum corneum of the epidermis at a rate of 2–3 mm/day, which are seen as thin twisting lines. The burrowing time is about 8 hours, mainly in the night. It feeds on liquid oozing from the cells it has chewed. It lays eggs in groups of 2–4/day and the total number of eggs laid is about 40–50.<sup>10</sup> The life cycle of *S. scabiei* is depicted in Fig. 51.4.

### SURVIVAL

The female mite survives away from the host for a maximum of 2–4 days at room temperature. The mites cannot use water vapor from air and must obtain water from the host. So fomites may not play a major role in the transmission of scabies.<sup>11</sup>

### EPIDEMIOLOGY

The incidence of scabies varies from time to time. The view that major scabies epidemics occur in 30-year cycles and last about 15 years is based largely on data from the 20th century, in which

Fig. 51.3: Terminal parts of ventral surface of adult male.

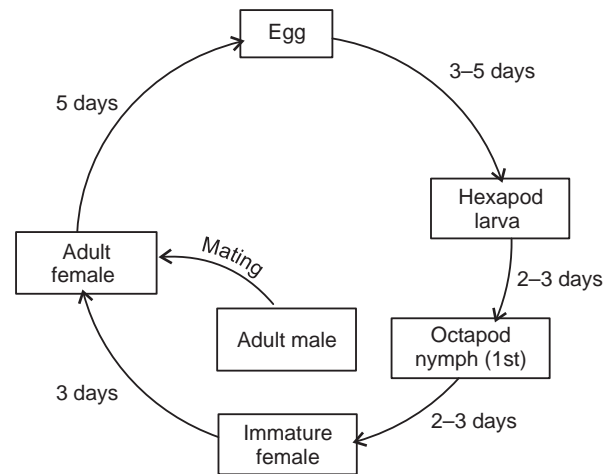

Fig. 51.4: Life cycle of *Sarcoptes scabiei*.

there had been three pandemics. Variations in herd immunity were postulated as the cause. Many authors have refuted this hypothesis. They argue that natural calamities, world wars, major economic depressions, and population movement were the major factors leading to the two pandemics which peaked in 1918 and mid 1945. Thus the frequently quoted 30 years cyclic period may be an oversimplification of the epidemiology of the disease.<sup>8</sup>

Scabies is a disease of the clean and the dirty, though the clinical profile may be different. Good personal hygiene serves little protection as shown in nosocomial outbreaks.<sup>12,13</sup>

Close physical contact, as in sharing a bed or sleeping crowded together, is the main mode of transmission. About 15–20 minutes of close physical contact is adequate for transmitting the disease. Fomites do not play a significant role in the transmission of scabies but reasonable precaution has to be taken in case of crusted scabies.<sup>8,11</sup> Though fertilized female mites are often implicated for transmission, there are far greater numbers of immature mites on the skin surface, which would appear more likely to be involved.<sup>6,8</sup> An infested person, during the incubation period is an important source of infection.

Scabies has been classified as a sexually transmissible disease, but the close physical contact, rather than the sexual act, could be responsible for the disease transmission.<sup>8</sup> In a study in Sheffield, England, “family contact” was focused as a major factor in the spread of scabies. The secondary attack rate within the family was 38%. The frequent sources for introduction of scabies into the home were friends and relatives (90%).<sup>14</sup>

In developing countries about 81% of scabies is seen in children below 14 years of age.<sup>12</sup> The rampant variety of scabies associated with HIV infection and other immunosuppressive states has resulted in hospital epidemics.<sup>8</sup>

## IMMUNOLOGY

The immune response to scabies mite is not absolute, but plays a major role in the epidemiologic studies and in the development of the clinical manifestations of scabies. Delayed hypersensitivity response plays a crucial role in eliminating the disease.<sup>15</sup> Some mite proteins have immunomodulating properties that facilitate host invasion by down regulating the inflammatory response of Langerhans and dendritic cells in the skin and possibly inhibiting a delayed immune reaction. Ordinary scabies induces a T-cell infiltrative response to the mite with a CD4+/CD8+ ratio of 4/1. Immunohistologic studies in crusted scabies reveal a predominantly CD8 + T-cell response. It is hypothesized that the activated CD8+ cells induce a dysregulated keratinocyte apoptosis and thus contribute to progressive epidermal hyperproliferation. The clinical appearance of crusted scabies is similar to that of psoriasis and suggests that the overexpression of Th1 cytokines may play a driving force in the dermatopathology.<sup>16</sup>

In primary infestation, the symptoms appear slowly after a lapse of about 4–5 weeks. The mite population is greatest during this incubation period. Once symptomatic, the mite population reduces dramatically. This is due to the mechanical removal of the mite by scratching and the immunological response by the host. Symptoms appear earlier (within 24–48 hours) in reinfestation. The rash is much more extensive and is not limited to the sites of infestation. Immunosuppressed patients appear particularly susceptible to severe forms of scabies. A high frequency of HLA A11 has been observed in scabies. Humoral immune response is also seen,<sup>15,17</sup> but its significance is not known. Crusted scabies is

associated with extremely high mite burden, elevated antibody levels, and eosinophilia.<sup>18,19</sup> The development of immunity neither ensures elimination nor does it confer immunity against reinfestation. Though the number of mites reduces, spontaneous cure, without treatment is not achieved.<sup>8</sup>

## CLINICAL FEATURES

### Classical Scabies

The diagnosis of scabies is essentially clinical. The primary lesions are burrows, papules, vesicles, bullae, and nodules. Burrows are the pathognomonic lesions and are 5–15 mm long linear eruptions. Erythematous papules are more common than burrows. They are more extensively distributed than mite bearing skin surface.<sup>20</sup> These lesions are referred to as “scabid.”

The lesions are distributed over the webs of the fingers, flexor medial aspect of the wrist, elbow, anterior axillary fold, nipple and areola in females, and genitalia in males. Lesions are bilaterally symmetrical. An imaginary circle, intersecting these main sites is called the “circle of Hebra.” The periumbilical region and lower portion of buttocks are also common sites of involvement. In infants and children, scalp, face, palms, and soles are also involved, which are characteristically spared in adults due to a high concentration of pilosebaceous follicles on the face and thick stratum corneum in palms and soles. Itching, usually generalized, is a predominant symptom and a nocturnal aggravation of pruritus is characteristic.

In adult males, scabietic lesions are sometimes seen only over the genitalia (Fig. 51.5a & b). These may indicate sexual transmission. They are raised, slightly elongated nodular lesions with the burrow tracks each seen as a thin, black, irregular line. Mechanical scratching by the patients removes the roof of the burrow leaving a shallow longitudinal ulcer. The lesions are commonly seen on the preputial skin, shaft of penis, scrotum, and glans penis.<sup>21</sup>

### Crusted Scabies

Crusted scabies (CS) was first described in Norway lepers by Danielssen and Boeck in 1842. Crusted scabies is remarkably asymptomatic in most of the cases in spite of the presence of more than two million organisms on the host, pointing towards the impaired immunological function.<sup>15</sup> It is characterized by marked crusting and scaly plaques, sometimes resembling psoriasis, in the usual scabietic sites. In addition, the palms, soles, head and neck, and lumbosacral areas may be involved. The helix of the ear is a constant site of involvement. CS may also present as erythroderma. Generalized lymphadenopathy may be present. Nails are dystrophic and discolored and masses of horny debris may accumulate under the nails.

Whenever CS is diagnosed, it is very important to find out the underlying associated conditions, like Down’s syndrome, Turner’s syndrome, neurological disorders with poor cutaneous sensation like Hansen’s disease or tabes dorsalis, and immunosuppression due

\*c+

\*d+

**Fig. 51.5:** (a) Scabietic lesions over the male genitalia; (b) Scabietic papules on prepuce.

to various causes, the most important of which is HIV infection.<sup>22–24</sup> Involvement of characteristic sites and occurrence of classical scabies in family contacts give a clue to the diagnosis.<sup>25</sup>

### Nodular Scabies

Nodular scabies is more common in young adult males. The persistent scabietic nodules present as reddish brown, extremely pruritic, excoriated nodules, 5–15 mm in size (Fig. 51.5b). Male genitalia and axillae are the common sites of involvement. Buttocks, anterior abdomen, and thighs are sometimes involved. It is associated with lesions of classical scabies in approximately two-third of patients. Patients with longer duration of untreated or inadequately treated scabies are more likely to develop nodular lesions. Lesions may persist despite antiscabietic therapy. In chronic cases, intralesional steroids are useful.<sup>26</sup>

### Scabies in Babies/Neonatal Scabies

The distinct features of neonatal scabies are the involvement of the face, neck, scalp, palms, and soles, in addition to the classical sites, tendency to form vesicles and pustules early in the course of the infestation, lack of pathognomonic burrows, presence of secondary eczematous changes, poor feeding, and failure to thrive. Examination of close contacts, especially the mother, may give a clue to the diagnosis.<sup>27,28</sup>

### Animal-Transmitted Scabies

Scabies affecting animals like dogs, cats, and pigs is called “sarcoptic mange.” Animal mites, though host specific, may accidentally be transmitted to humans, but cannot complete their life cycle. Animal scabies is found in occupations typified by names such as “dairyman’s itch,”<sup>8</sup> “cavalryman’s itch,” and “Buffaloman’s itch.”<sup>8</sup> Scabies contracted from dogs has been described as “pseudoscabies.”

It has a shorter incubation period of 1–10 days. It is common in children and seen at sites of contact with the animal, e.g., flexor forearm, lower part of chest and abdomen. Burrows are usually absent. The course is self-limited once the contact with the animal is avoided, although good results have been achieved with treatment. There is no need to treat the contacts.<sup>29</sup>

### Scabies Incognito

Scabies treated with topical or systemic steroids presents with an unusual clinical manifestation with bizarre crusted lesions involving atypical sites. The itching is less, but the mite population is more.

### Scabies in Clean

Lesions are few and are commonly seen on the genitalia and thighs. Other classical sites are usually spared. Papules are seen but burrows are uncommon. They may present as nodular lesions or chronic urticaria.<sup>26</sup>

### Scabies in Bedridden

Bedridden patients may have scabies limited to the sites of constant contact with the sheets.<sup>8</sup>

### Scabies Galeuse/Chancre Galeuse

Rarely, an individual with scabies may acquire syphilis. As a result, a syphilitic chancre can occasionally occur in a cutaneous lesion of scabies.<sup>26</sup> The initial lesion of scabies may be the route of entry for *Treponema pallidum*.<sup>21</sup>

### COMPLICATIONS

The common complications of scabies and its sequelae are secondary bacterial infection, glomerulonephritis (immune complex mediated), post-scabietic pruritus, and persistent delusions of parasitosis.<sup>20</sup> Secondary bacterial infections in genital region may result into inguinal lymphadenopathy, and

**Fig. 51.6:** Inguinal lymphadenopathy due to secondarily infected scabies.

sometimes, bubo formation (Fig. 51.6). Septicemia, bacterial endocarditis, and death have been reported in association with scabies, especially in immunocompromised hosts.<sup>30</sup>

## DIAGNOSIS

Diagnosis of scabies is essentially clinical. The classical diagnostic features are the demonstration of burrows, distribution of lesions at the characteristic sites, nocturnal aggravation of pruritus, a family history of scabies and demonstration of the mite, ova, immature stages, or the scybala (fecal matter).<sup>20</sup>

Laboratory techniques for the identification of burrows include mineral oil application to the skin surface, tetracycline fluorescence test, and the Burrow-ink test. The definitive diagnosis of scabies is by the demonstration of the mite or its products under microscopy (Figs. 51.1 and 51.7a&b). Scrapings are examined under low power (10×) after addition of a few drops of 10% potassium hydroxide solution.

Epiluminescence microscopy has been used to demonstrate the mite and the burrow. Electron microscopic and scanning electron microscopic features are also described, but are not useful in routine clinical practice. In the future nested PCR may prove to be a useful tool for diagnosing scabies in those in whom disease is clinically suspected but mites had not been detected.<sup>31</sup>

## DIFFERENTIAL DIAGNOSIS

John Stokes states that scabies is both the easiest and yet the most difficult diagnosis in dermatology.<sup>26</sup> Scabies has to be differentiated from the following diseases: (i) papular urticaria or insect bite reaction, in which the lesions are mainly distributed on the exposed areas; (ii) dermatitis herpetiformis, the classical distribution of lesions on the upper back and lumbosacral areas, and grouping of lesions help differentiate it from scabies; (iii) contact dermatitis, history and presence of classical features of scabies help rule out contact dermatitis; and (iv) atopic dermatitis is at times difficult to differentiate from scabies in children, as it presents as acute eczema. A positive history of atopy, absence

\*c+

\*d+

**Fig. 51.7:** (a) Immature eggs of *Sarcoptes scabiei*; (b) Mature eggs of *Sarcoptes scabiei*.

of scabietic lesions at the classical sites, and absence of a family history of scabies are useful clues to the diagnosis.<sup>20</sup>

## MANAGEMENT

### General Measures

- Treat the patient, household, and close contacts simultaneously regardless of whether they have symptoms of infection or not.<sup>32</sup>
- Before applying the medication a bath or shower is advised. A scrub bath is not indicated, especially prior to application of lindane.
- Drug should be applied to the whole body from neck down. In infants and in patients with CS, the drug should be applied on head and neck also.<sup>33</sup>
- Bedding and clothing should be washed.

## Specific Therapy

Oral and topical antiscabietics are available. The common topical scabicides include precipitated sulfur, tetmosol, crotamiton, benzyl benzoate, lindane, and permethrin. Currently, oral ivermectin has been found to be effective. Precipitated sulfur (as 6% ointment in petrolatum) for three consecutive nights was used in the past. It is very cheap and safe even in infants and pregnant women. It is no longer used because it is messy, stains clothes, and has an unpleasant odor.<sup>33</sup> Tetmosol (tetraethylthiuram monosulfide) as a 25% solution and 5% medicated soap is available but rarely used.

Crotamiton cream or lotion 10% is used, mainly in children. The cure rate is only 60%. It has a good antipruritic action. Single daily application for two consecutive days is recommended. Some suggest that daily application for 5 days may be better than the 2 days currently recommended.<sup>34</sup>

Benzyl benzoate 25% emulsion is widely used in developing countries. It has to be left on the skin for at least 48 hours. It is cheap and effective, but may cause irritation occasionally.<sup>33</sup> Benzyl benzoate may serve a larger role in therapy given the emergence of drug-resistant scabies. It has been found to be effective in permethrin-resistant Norwegian scabies and in combination with ivermectin in patients with relapse after single treatment with ivermectin.<sup>35,36</sup>

### Lindane 1% (Gamma Benzene Hexachloride) Lotion

It is an organochloro compound having miticidal, larvicidal, and ovicidal activity. Lindane is no longer recommended as first-line therapy because of toxicity. It should only be used as an alternative if the patient cannot tolerate other therapies or if other therapies have failed. Lindane resistance has been reported in some areas of the world, including parts of the United States. Lindane should not be used immediately after a bath or shower, and it should not be used by persons who have extensive dermatitis, patients with a history of a seizure disorder, women who are pregnant or lactating, or children aged <2 years of age. Seizures have occurred when lindane was applied after a bath or used by patients who had extensive dermatitis. Aplastic anemia after lindane use also has been reported. If lindane is used, a single overnight application is generally recommended.<sup>33–39</sup>

### Permethrin 5% Cream

Permethrin, a synthetic pyrethroid, is a very effective insecticide used widely in agriculture, livestock, and protection of foods and grains in storage. “Pyrethrum” is the common name for the dried flowers of *Chrysanthemum cinerariaefolium*. “Pyrethrins” are the active insecticidal component of pyrethrum. The identification of the structure of these natural pyrethrins led to the development of synthetic insecticides called pyrethroids.<sup>40</sup>

Although permethrin is highly toxic to arthropods, it is one of the least toxic to mammals. The mean systemic absorption of topical permethrin, over the first 48 hours is approximately 0.5% of the applied dose with a maximum of 2.08% (10% absorption for lindane). As a result, the toxic effects are minimal.<sup>41,42</sup>

Permethrin acts on the parasite’s nerve cell membrane to disrupt the sodium channel current. This causes a delayed repolarization, paralysis, and death.<sup>43,44</sup>

Permethrin is superior to all presently available antiscabietics and is the treatment of the choice in scabies. It has a high cure rate of 91–98%.<sup>42,45</sup> Adverse reactions are few (2%), which include burning sensation, erythema, edema, rash, allergic (to the preservative—formaldehyde) and irritant contact dermatitis.<sup>44</sup> The main advantages are its safety of use even in infants, children, and pregnant women, less expensive than ivermectin, high efficacy and a simple, single, overnight application.

### Ivermectin

Ivermectin is a derivative of a family of macrocyclic lactones, the avermectins, which was found in the fermentation broth of one of the actinomycete cultures (*Streptomyces avermitilis*) received from the Kitasato Institute in Japan. It is named “ivermectin,” because of its action against endoparasites and ectoparasites.<sup>46</sup>

Ivermectin binds selectively and with high affinity to glutamate-gated chloride ion channels, which occur in invertebrate nerve and muscle cells. This leads to an increase in the permeability of the cell membrane to chloride ions (which is independent of GABA-mediated chloride channels) with hyperpolarization of the nerve or muscle cell resulting in paralysis and death of the parasite. Ivermectin does not readily cross the blood-brain barrier (BBB). This adds to its safety in mammals.<sup>47–49</sup>

The half-life is approximately 12 hours. Ivermectin and its metabolites are excreted mainly in feces (99%). It is active against at least one stage of the life cycle of the parasite. It is effective in nematode infestations, cutaneous larva migrans, onchocerciasis, filariasis, scabies, and head lice infestations.<sup>50,51</sup>

It is available as 3 and 6 mg white scored tablets and also as a liquid preparation for oral and topical use.<sup>52–54</sup> Studies have shown that a dose of 200 µg/kg body weight is effective in scabies, and the cure rates are better, if the dose is repeated after 10–14 days.<sup>55</sup>

No major side effects directly attributable to ivermectin have been observed. The mild and transient side effects include headache, pruritus, rash, arthralgia, and dizziness. Mazzotti reaction, characterized by major features like fever (>40°C), orthostatic hypotension, bronchospasm, neurological deterioration, and minor features like itching, rash, arthralgia, and headache have been observed. This has been linked to a systemic hypersensitivity reaction to dead and dying parasites.<sup>53</sup> One study demonstrated increased mortality among elderly, debilitated persons who received ivermectin, but this observation has not been confirmed in subsequent reports.

It is better avoided in patients with neurological disorders and in those with impaired blood-brain barrier.<sup>56,57</sup> Safety of ivermectin in pregnant women and children below 5 years of age has not been established. However, recent studies report its safe use in children as young as 14 months of age.<sup>58</sup>

The advantages of ivermectin are the simplicity of oral administration, good patient compliance, and safety.<sup>59</sup> Community-

based treatments will be greatly simplified. Crusted scabies associated with HIV infection responds well to ivermectin.<sup>60,61</sup>

### Treatment of Crusted Scabies

Crusted scabies (i.e., Norwegian scabies) is an aggressive infestation that usually occurs in immunodeficient, debilitated, or malnourished persons. Patients who are receiving systemic or potent topical glucocorticoids, organ transplant recipients, mentally retarded or physically incapacitated persons, HIV-infected or human T-lymphotrophic virus-1-infected persons, and persons with various hematologic malignancies are at risk for developing crusted scabies. Crusted scabies is associated with greater transmissibility than scabies. No controlled therapeutic studies for crusted scabies have been conducted, and the appropriate treatment remains unclear. However, observational studies demonstrate the effectiveness of ivermectin for crusted scabies when topical therapies have failed. Substantial treatment failure might occur with a single topical scabicide or with oral ivermectin treatment. Some specialists recommend combined treatment with a topical scabicide and repeated treatment with oral ivermectin 200 µg/kg on days 1, 2, 8, 9, and 15. Additional treatment on days 22 and 29 may be required for severe cases. Ivermectin should be combined with the application of either 5% topical benzyl benzoate or 25% topical permethrin (full body application to be repeated daily for 7 days then 2 × weekly until discharge or cure). Lindane should be avoided because of the risks for neurotoxicity with heavy applications or denuded skin. Patient's fingernails should be closely trimmed to reduce injury from excessive scratching.<sup>39,62</sup> Combination with topical scabicides gives better results along with the standard management of crusted scabies, like nail trimming, applications of keratolytics or antiscabietics in the subungual regions, fomite control, and treatment of all contacts.

### HIV AND SCABIES

Worldwide, there are reports of bizarre forms of scabies occurring in at least 2–4% of patients with HIV infection.<sup>63</sup> The unusual forms of scabies in AIDS can present as crusted scabies or atypical exaggerated scabies. It is common to present initially with ordinary scabies, and as they become progressively immunosuppressed, convert into crusted scabies. In many patients, the pruritus of ordinary scabies lessened or disappeared when the conversion to crusted scabies took place.<sup>64</sup> Crusted or thick whitish-gray plaques, discrete or generalized, in a young patient, should alert the clinician to the possibility of crusted scabies with immunosuppression. Crusted scabies in HIV infection may resemble Darier's disease or psoriasis.<sup>60</sup> The serious problem faced in these patients with crusted scabies is the prominent fissuring leading to bacteremia and death. Wide spectrum of clinical manifestations are seen, with only a few erythematous papules to widespread papules to crusted scabies. The atypical lesions of scabies may resemble pruritus of AIDS, pruritic papular eruption, generalized dermatitis resembling drug

reaction, contact dermatitis or dermatophytosis.<sup>60</sup> Patients with low CD4+ T-cell counts harboring large number of mites present with a diffuse papular eruption referred to as “anergic scabies.” Patients can present with severe pruritus without any clinical signs, but yield numerous mites on scraping. Scabies should be suspected in any atypical itching or asymptomatic rash in patients with HIV/ AIDS. It is very important to prevent the nosocomial spread of scabies from these highly contagious patients. Skin scrapings should be performed and an excellent site for scraping is under the fingernails. HIV-related scabies is more difficult to treat. Ivermectin is the drug of choice in these patients. Concurrent application of a topical scabicide, preferably 5% permethrin cream 2–3 times a week for 6 weeks, gives better results.<sup>60</sup> Concomitant use of keratolytics (3–6% salicylic acid in petrolatum) hastens the removal of crusts.

### Pediculosis Pubis (Phthiriasis)

Pediculosis is an ectoparasitic infestation caused by lice. Human lice belongs to class Insecta, order Phthiraptera and suborder Anoplura. Humans are parasitized by two species, *Pediculus humanus* (head and body louse) and *Phthirus pubis* (pubic louse).

Infestation by pubic louse or crab louse is seen mostly in young adults, transmitted usually by sexual contact. The incidence of the condition increases with increase in the number of sexual partners. It may be acquired by skin-to-skin contact and also from public toilet seats, bathing facility or rarely contaminated bedding or towels. The prevalence seems to be lower in geographic areas where extensive removal of pubic hair, like the “Brazilian wax” is more common. Infection is reported to be more frequent in whites.<sup>65</sup> About 38% of cases with pubic lice have one or more of the other sexually transmitted infections (STIs),<sup>66</sup> which points to its sexual mode of transmission but also indicates a need to screen for other STIs when pubic lice are diagnosed.

### MORPHOLOGY

The pubic or crab louse has a distinct appearance. The adult female louse is dorso-ventrally flattened and has a head with a pair of antennae and mouth parts, a thorax with three pairs of legs each of which ends in a claw, and an abdomen (Fig. 51.8). The pubic louse has a broad, short, grey body, about 1.5–2 mm long. The first pair of legs is more slender than the other pairs. The heavy pincer-like claws help the crab louse to grip adjacent hairs. Eggs are laid in groups of 20–30 and are glued to the hair of the host. Eggs hatch in about 1 week and mature into an adult in 2–3 weeks.

They have a life expectancy of about 1 month.

### CLINICAL FEATURES

Itching in the pubic region is the predominant symptom. Close inspection reveals the presence of lice grasping the pubic hairs close to the skin surface and eggs glued to the hair shafts. The lice are seen mainly in the hair of the pubic region, but in severe

Fig. 51.8: Pubic louse.

cases they may be seen on the hair of moustache, beard, axillae or eyelashes. Scalp hair is usually spared.

Pruritic red papules with central punctum, which becomes excoriated and impetiginized, may also be seen. Bluish and steel grey asymptomatic macules called “maculae cerulae” are useful diagnostic sign. They are more frequently seen on the lower abdomen and thighs.<sup>67</sup> This may be due to an altered blood pigment or a reaction to saliva of the louse. The condition may be asymptomatic in nearly half of the infected cases, as they may not show any reaction to the bite of the louse that may remain attached to the skin, feeding on blood intermittently. It is unable to survive for more than 2–3 days without a blood meal. Severe pruritus and secondary infection may be the only sign of infestation.

The diagnosis is confirmed by demonstrating the louse or nit. The lice are seen as yellowish brown to dark brown specks attached to the base of the hair. The nits are attached to the hair at an acute angle. The presence of pediculosis pubis is an indication to look for other STIs.<sup>68</sup>

## TREATMENT

Gamma benzene hexachloride applied to the entire body below the neck for 12 hours is usually effective. Permethrin 1%, applied for 10 minutes and rinsed off is an effective alternative. There have been some reports of resistance to permethrin and follow-up examinations are indispensable for the clinician to confirm complete removal of crab louse.<sup>69</sup> Benzyl benzoate and crotamiton are other modalities of treatment. Shaving of pubic hair may not be beneficial. Treatment of partner is mandatory as in the case of other STIs. When eyelashes are involved the treatment is rather difficult. Although mechanical removal of lice and eggs with fine forceps or epilation of the lashes with their attached eggs are obvious methods for dealing with eyelash infection, these procedures are uncomfortable and not usually recommended. Several other methods of treating crab lice on the eyelashes have been suggested, including cryotherapy, application of one or two drops of freshly prepared 20% fluorescein eye drops to the lid margin,<sup>70</sup> petrolatum, and physostigmine eye ointment.

Petrolatum can be applied thickly twice daily for a few days. A drawback of physostigmine is that it paralyzes accommodation and causes blurred vision if introduced into the eye. Modern insecticide preparations may be used to treat crab louse on the eyelashes, but alcohol-based preparations are irritant, if inadvertently introduced into the eye, and aqueous preparations such as malathion 0.5% liquid are preferable.

There may be reluctance to accept the use of pesticide creams as treatment for pubic lice. They remain the only effective treatment, other than physical removal of the lice. Health concerns related to the use of topical pesticides and the belief that oral antibiotics are effective therapy are potential barriers clinicians may need to address when treating patients.<sup>71</sup>

## Conclusion

There is an increasing worldwide incidence of scabies and pediculosis. In addition, reports of increasing rate of resistance to commonly used scabicides have become a major issue.<sup>63</sup> Scabies has been classified as a sexually transmissible infection, even though close physical contact without sexual contact is sufficient for transmission. On the other hand, crab louse is usually transmitted by sexual contact. Of the topically applied medications used for scabies, 5% permethrin has been found to be the most effective agent. Lindane is not recommended as first-line therapy because of toxicity. It should only be used as an alternative if the patient cannot tolerate other therapies or if other therapies have failed.

For the treatment of pediculosis, 1% permethrin and pyrethrins with piperonyl butoxide applied to the affected area and washed off after 10 minutes have been found to be most effective. Reported resistance to pediculicides has been increasing and is widespread. Malathion may be used when treatment failure is believed to have occurred because of resistance. All family members and close contacts of patients with scabies or pediculosis should be treated simultaneously. Patients should be informed that post-treatment pruritus can persist for several weeks.

## The Syndromic Approach for the Management of STIs: An Overview

Ahmed S. Latif

### Introduction

Sexually transmitted infections (STIs) are caused by microbial agents that are passed on from person to person at the time of sexual intercourse. STIs are of public health concern not only because of their high prevalence worldwide but also because of their potential to cause serious and permanent complications in persons who are infected and are not treated in a timely and effective way.<sup>1,2</sup> In addition, STIs increase the risk of acquisition and transmission of the human immunodeficiency virus (HIV), the causative agent of AIDS.<sup>3-6</sup>

STIs occur in adults and children. Neonates and infants may become infected as a result of vertical transmission of infection from the mother. Complications of STIs may be serious and include infertility in men and women, an increased risk of ectopic pregnancy in women and blindness and deformities in children. Some complications of STIs in women may be life threatening. Table 52.1 summarizes the complications that may be caused by different STIs. Persons with STIs, both men and women, may remain asymptomatic for varying periods of time and often develop symptoms only when complications occur.

Control of STIs may be achieved through primary or secondary prevention activities. In primary prevention activities, the goal is to prevent the acquisition of STIs through adopting safer sexual behavior and engaging only in safer sex acts. Secondary prevention of the transmission of STIs may be achieved through promoting STI care-seeking behavior, and by rapidly and effectively treating persons with STIs, identifying and treating persons who may have STIs but have only minimal symptoms, and those at greater risk of acquiring STIs.

The objectives of any STI control program are to reduce the incidence and prevalence of STIs, the incidence of STI-related complications, and the sexual transmission of HIV infection.

### Provision of Care for Persons with STIs

High-quality, effective, and acceptable STI care should be available at all health facilities in the private and public sectors and healthcare facilities providing STI care should be accessible

to care seekers. The provision of STI care through categorical STI clinics is at times considered unacceptable as STI care seekers feel stigmatized and fear being identified by the public. This results in the care seeker seeking care elsewhere. Unfortunately, the alternate care providers may not be able to provide the most effective and complete care of the patient. The advantage of having a designated STI clinic is that specially trained personnel and laboratory testing facilities can be made available at the centre and hence all the needs of the care seeker can be met. However, to avoid stigmatization, persons with STIs prefer to attend facilities where they feel that their privacy and confidentiality will be maintained, and they will be treated like any other patient.

STI care is considered acceptable if the care provided is effective in relieving symptoms, preventing complications from occurring, and the care is provided in a non-judgmental and non-moralizing manner without any form of discrimination. It is ideal, therefore, to ensure that all health centers are capable of providing high-quality, acceptable care for persons with STIs. Healthcare providers at the peripheral level, however, often feel that they are unable to provide adequate care as they neither have the expertise or the laboratory facilities to make a correct clinical or

**Table 52.1:** Complications and Causes of STIs

Complications	Causes
Infertility in men and women	Gonococcal and chlamydial infection
Urethral stricture in men	Gonococcal and chlamydial infection
Blindness in infants	Gonococcal infection
Ectopic pregnancy	Gonococcal and chlamydial infection
Pelvic and generalized peritonitis	Gonococcal, chlamydial, anaerobic bacterial infection
Permanent brain and heart disease	Acquired syphilis
Extensive organ and tissue destruction in children	Congenital syphilis
Genital cancer	Human papilloma virus

etiological diagnosis. This is essentially true as making a diagnosis based on finding the etiologic agent causing the infection requires sophisticated laboratory tests and these will not be available at most health centers. Fortunately, however, it is not necessary, in most cases, to make a laboratory-based etiologic diagnosis before providing effective care. In fact, the laboratory tests may even be misleading and may not be able to provide the answers that the healthcare provider is searching for. High-quality, effective STI care may be provided at all health facilities without the need to make a laboratory diagnosis. This may be achieved through the syndromic case management approach.

## Making Diagnosis of STI

The diagnosis of STI may be made in three ways. Firstly, a specific clinical diagnosis may be made after taking a history and examining the patient. From the symptoms and signs, and past clinical experience, a specific diagnosis of the infection is made. Secondly, an etiological diagnosis of STI may be made after positively identifying the causal agent of the symptoms and signs. This requires the taking of specimens from the patient and sending them to a laboratory for appropriate tests. The laboratory will then attempt to identify the pathogen that is causing the symptoms. Thirdly, a syndromic diagnosis of STI may be made after taking a history and examining the patient and identifying the pattern of symptoms and signs that make up a syndrome. This is also a clinical diagnosis.

Each method of making a diagnosis has advantages and disadvantages and these are shown in Table 52.2.

Most commonly throughout the world the diagnostic approaches used include making an etiological diagnosis or making a syndromic diagnosis. The making of a specific diagnosis of an infection through clinical experience is too inaccurate, and hence is not used widely. The diagnostic approaches outlined above are useful if persons present with symptoms and signs related to STIs. However, if a person attends a health facility without any symptoms or signs then the only way to exclude infection is by carrying out laboratory tests.

### MAKING CLINICAL DIAGNOSIS

A clinical diagnosis is made after a history is taken and an examination is carried out. The making of the diagnosis is dependent on the past experience of the clinician. The diagnosis is often inaccurate and different clinical presentations of pathogens may lead to confusion in making a diagnosis. Mixed infections are often missed and a patient may be treated for an infection that he/she does not have. If there is mixed infection the patient may respond partially to treatment and may resume sexual activity with the risk of spreading infection and developing complications.

### MAKING ETIOLOGICAL DIAGNOSIS

In order to make an etiological diagnosis it is necessary to identify the organism that is causing the infection. This requires a laboratory that is capable of carrying out microbiologic and

**Table 52.2:** Advantages and Disadvantages of the Different ways of Making a Diagnosis of STI

Diagnosis	Advantages	Disadvantages
<b>Clinical diagnosis</b>	Patient may be treated for a single infection if the diagnosis is correct	Clinical expertise and experience needed Even with great experience the diagnosis is incorrect in 50% of cases Mixed infections may not be diagnosed Patients may improve transiently and hence could further spread the infection
<b>Etiological diagnosis</b>	Most accurate method of diagnosing a specific infection Treatment may be aimed at a single infection	Need for laboratory capable of identifying and isolating organisms and carrying out blood tests Need for personnel and equipment Need for finances to run the laboratory Expensive Delay in commencing treatment if results of tests are awaited False positive and false negative test results may occur Need for training
<b>Syndromic diagnosis</b>	Allows for diagnosis and treatment at one visit No special tests are necessary to make a diagnosis Diagnosis can be made at all levels of the health infrastructure and a broad range of health workers can use this method Patient can be provided with effective care without delay Simple, inexpensive and reliable Cost effective method of diagnosis	Patient is treated for more than one infection Need for training Possibility of overtreatment as patients will be treated for more than one infection each time

serologic tests on specimens taken from a person who is suspected of having an infection. Table 52.3 shows the tests that need to be carried out in order to establish an etiologic diagnosis and the type of specimen that needs to be submitted to the laboratory. Provided that the clinic has some laboratory equipment and personnel trained and experienced in performing tests, it may be possible to carry out some of the tests while the patient waits at the clinic. The tests that may be performed quickly and reliably at the clinic include:

- Gram-staining and microscopy
- Microscopic examination of fresh wet mounts of secretions

**Table 52.3:** Laboratory Tests Needed to be Performed in Order to Establish an Etiologic Diagnosis of STI

Diagnosis	Specimens needed	Tests to be carried out
<b>Early syphilis</b>	Fresh exudates from moist lesions or lymph node aspirates Venous blood	Dark field microscopy to identify <i>T. pallidum</i> Serological tests for syphilis
<b>Latent syphilis</b>	Venous blood	Serological tests for syphilis
<b>Chancroid</b>	Fresh ulcer exudates or bubo aspirates	<i>H. ducreyi</i> culture and identification Nucleic acid amplification tests for detecting <i>H. ducreyi</i> nucleic acid
<b>Gonorrhea</b>	Smears and swabs of urethral discharge and cervical discharge	Microscopy of gram stained smears of discharge <i>N. gonorrhoeae</i> culture and identification Nucleic acid amplification tests for detecting <i>N. gonorrhoeae</i> nucleic acid
<b>Chlamydial infection</b>	Smears and swabs of urethral discharge and cervical discharge	Antigen detection by fluorescent microscopy <i>C. trachomatis</i> culture and identification Nucleic acid amplification tests for detecting <i>C. trachomatis</i> nucleic acid
<b>Granuloma inguinale</b>	Deep smears of ulcer exudates or biopsy of ulcers	Microscopy of Giemsa stained smears Nucleic acid amplification tests for detecting <i>K. granulomatis</i> nucleic acid Histology of tissue biopsies
<b>Genital herpes</b>	Smears and swabs of ulcer exudates	Antigen detection by fluorescent microscopy Antigen detection by ELISA tests Herpes simplex culture Nucleic acid amplification tests for detecting herpes simplex virus nucleic acid
<b>Trichomoniasis</b>	Fresh swabs of genital discharge	Microscopy of wet preparations <i>T. vaginalis</i> culture and identification
<b>Candidiasis</b>	Smears and swabs of genital discharge	Microscopy of gram-stained smears of discharge <i>C. albicans</i> culture and identification
<b>Bacterial vaginosis</b>	Fresh swabs of genital discharge	KOH test Microscopy of gram-stained smears Anaerobic culture of material (Note: Clinical criteria are necessary)

- Rapid plasma regain (RPR) test—a non-specific test for syphilis performed on patients' serum
- Rapid specific test for syphilis—a number of rapid tests for syphilis are now available commercially

- A urine examination for polymorphonuclear leukocytes by using the leukocyte esterase (LE) dip stick method. This test provides indirect evidence for gonococcal and/or chlamydial urethritis in men; the test however is neither sensitive nor specific for these infections.

The laboratory technologist at the clinic can also ensure that the specimens that are to be sent away for tests at another laboratory are properly catalogued, labeled, and packaged for transport.

Making an etiologic diagnosis of STI is associated with a number of problems. It requires a well-equipped laboratory and trained personnel. Laboratory testing costs money and tests take time to be carried out and therefore there are delays in commencing treatment. Tests available are not foolproof and the sensitivity and specificity of commercially available tests varies significantly. This affects the reliability of tests in making an accurate diagnosis. In addition, there is a need to establish strict external quality control measures. Currently only gram-stain and microscopy, urine microscopic examination, and non-specific syphilis serology can be performed at primary care clinics in most developing countries. The availability of rapid specific tests for syphilis is improving in many countries and this will improve testing for syphilis at the first point of care.

### MAKING SYNDROMIC DIAGNOSIS

The syndromic approach to the diagnosis of STIs is based on the fact that a number of sexually transmissible pathogens produce a common pattern of easily recognizable symptoms and signs. This approach in making a diagnosis of STI is only applicable to those persons with STI who present with symptoms and signs. Since making a syndromic diagnosis is based on the presence of symptoms and/or signs this approach is not applicable in persons with infection who are asymptomatic.

In persons with symptoms and signs this approach is most useful in terms of practicability and in terms of cost effectiveness. Sexually transmissible pathogens produce a small number of syndromes. The syndromic management of STI is based on the identification of the STI-related syndrome, and the provision of treatment that will deal with the majority or most serious organisms responsible for producing a syndrome. The syndromes and their causes are shown in Table 52.4.

Infection with most of the sexually transmissible pathogens results in the development of a pattern of symptoms and signs. A collection of symptoms and signs, resulting in a clinical pattern, is known as a syndrome. It is not difficult clinically, therefore, to recognize an STI by the clinical syndrome it produces. Though STIs are caused by a large number of different pathogens, a number of these different pathogens produce a common set of symptoms and signs.

As an example, it is known that a common cause of urethral discharge in men is *Neisseria gonorrhoeae*, the causal agent of gonorrhea. However, it cannot be stated that if a man has a urethral discharge then he always has gonorrhea. We know that urethral discharge may be caused by pathogens other than those that cause

**Table 52.4:** STI-Related Syndromes and Their Causes

STI syndrome	Causes of the syndrome
Urethral discharge	<i>N. gonorrhoeae</i> , <i>C. trachomatis</i>
Genital ulcers	<i>T. pallidum</i> , <i>H. ducreyi</i> , Herpes simplex virus, <i>K. granulomatis</i> , <i>C. trachomatis</i>
Vaginal discharge syndrome	<i>N. gonorrhoeae</i> , <i>C. trachomatis</i> , <i>T. vaginalis</i> , <i>C. albicans</i> , and anaerobic bacteria
Suppurative inguinal lymphadenitis (Bubo)	<i>H. ducreyi</i> , <i>C. trachomatis</i>
Lower abdominal pain (women)	Pelvic inflammatory disease – caused by <i>N. gonorrhoeae</i> , <i>C. trachomatis</i> and other bacteria
Acute scrotal swelling	<i>N. gonorrhoeae</i> , <i>C. trachomatis</i> and other bacteria and viruses
Neonatal purulent conjunctivitis (ophthalmia neonatorum)	<i>N. gonorrhoeae</i> , <i>C. trachomatis</i> and other bacteria

gonorrhea. These include *Chlamydia trachomatis*, *Trichomonas vaginalis*, and *Mycoplasma genitalium*. All these are organisms that can cause urethral discharge in men. It can therefore be stated that the syndrome of urethral discharge may be caused by any of these pathogens. In order to determine the exact cause of the discharge, laboratory tests need to be carried out. The tests that are needed are complicated to perform, expensive, and it may take some days for the results to become available. The patient can neither wait for the results before he is treated, nor should he wait. As we know that a number of different organisms can cause the symptoms and signs the best thing to do is to treat the patient for all the organisms that are known to cause the syndrome. But this would be unacceptable overtreatment. In practice what we do, however, is give the patient treatment for the common causes of urethral discharge in the country or region. We know from studies carried out that the common causes of urethral discharge are *N. gonorrhoeae* and *C. trachomatis*. Therefore, all men who come to us with urethral discharge syndrome we will treat for gonococcal and chlamydial infection in the first instance. In this way the patient is not only relieved of his symptoms, but he is also rendered non-infectious as quickly as possible, and the risk of him developing complications and further transmission is reduced.

Similarly for persons presenting with genital ulcers a diagnosis of genital ulcer syndrome is made; the common causes of genital ulcer syndrome are genital herpes, syphilis and chancroid, though in some parts of the world other causes of genital ulcers such as granuloma inguinale (Donovanosis) and lymphogranuloma venereum are also commonly found. It is important therefore that epidemiologic studies are carried out periodically.

### RISK ASSESSMENT IN MAKING DIAGNOSIS OF STI

In order to assist in making a diagnosis of STI, it may be possible to carry out a risk assessment for STIs. In general it may be assumed that persons with STI have engaged in risky sexual behavior and risky sexual activity. Any person who has

unprotected sexual intercourse with a non-regular partner has placed himself/herself at risk for STI. Similarly, any person who has multiple sexual partners, engages in frequent partner change, engages in commercial sexual activity or has sex with a partner who has an STI, is at risk for acquiring STIs.

By carrying out a risk assessment it may be possible to make a diagnosis of STI with greater certainty and provide appropriate care to patients. Risk assessment is particularly useful when managing women with vaginal discharge: women with vaginal discharge may have vaginitis, which is caused by trichomoniasis, candidiasis or bacterial vaginosis, or, they may have cervicitis, which is caused by gonococcal or chlamydial infection. Commonly, women with vaginal discharge have both vaginitis and cervicitis. Clinically it is extremely difficult to distinguish between the two main causes of vaginal discharge especially since both causes may be present. Vaginitis is the usual and more frequent cause; however, cervicitis is the more serious cause as the pathogens that cause cervicitis can lead to serious complications. A thorough clinical examination will also not help in excluding vaginitis from cervicitis. Apart from carrying out complex laboratory tests, there is no easy method of distinguishing between vaginitis and cervicitis.

Studies have shown that in women with vaginal discharge the following risk factors are indicative of the presence of cervicitis:

- The partner has an STI
- The patient is aged less than 21 years
- The patient is not married
- The patient has had sexual contact with a new partner in the last 3 months
- The patient has had sexual contact with more than one partner in the last 3 months

These risk factors are not universally applicable and vary from place to place. There is a need to determine locally the risk factors associated with cervicitis in women with vaginal discharge. However, until such time that local risk factors have been identified it is advisable to use the risk factors listed above. It is recommended that a woman with vaginal discharge be considered to have a positive risk assessment for cervicitis if she admits that her partner has an STI or if she has any other two of the risk factors listed above. Hence, all female sex workers with vaginal discharge are risk-assessment positive for cervicitis and should be treated. The use of risk factors in asymptomatic subjects has not been evaluated extensively. There is a need for more studies to be carried out in order to address this problem.

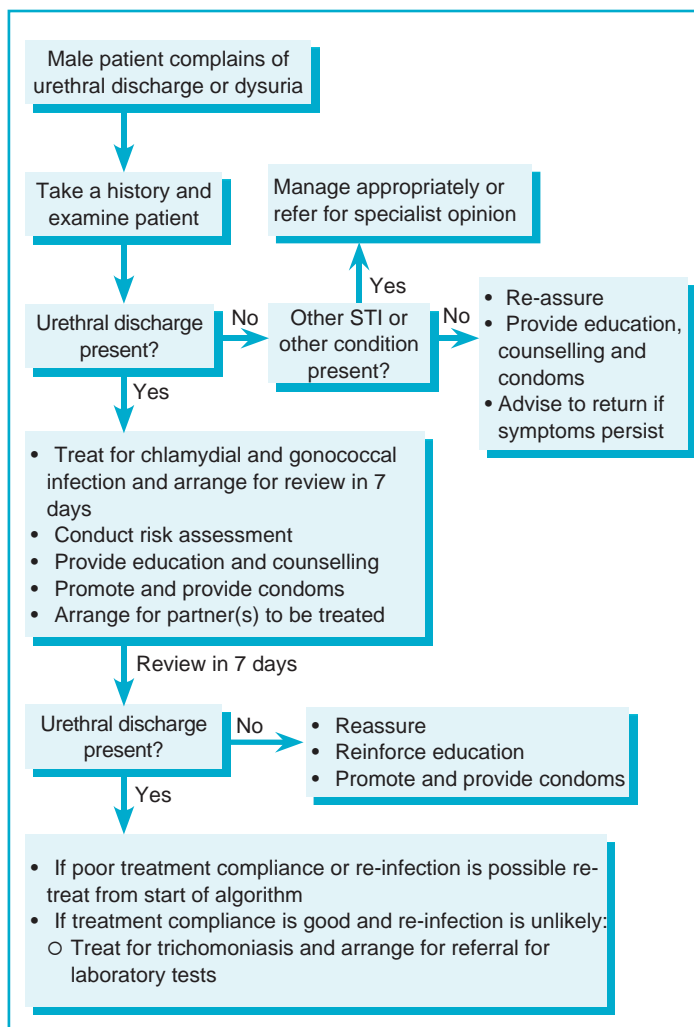

### Syndromic Case Management of STIs

Once a syndromic diagnosis of the STI is made, the patient may be offered treatment. However, the simple provision of antibiotics is not enough. All patients with STIs should be given the complete care “package”. Patients with STIs have become infected through their own or their partner’s risky sexual behavior and have placed themselves at risk of becoming infected with HIV as well. All healthcare providers should take advantage of the STI consultation to provide the patient

with the means of avoiding becoming infected in the future. Regardless of the manner in which the diagnosis of STI has been made (i.e., syndromic or etiologic) all patients with STIs should be offered as a minimum:

- Appropriate antibiotic treatment for the infection diagnosed or for the STI syndrome diagnosed
- Health education on the nature of the infection
- Health education on ways to avoid becoming infected in the future through safer sexual behavior and safer sex activity
- Counseling after an assessment of the patient's own perception of risk for STI and reasons for risk-taking
- Health education on the importance of treatment compliance
- Education on the correct use of condoms
- A supply of condoms
- Information on how the patient's partner(s) can also be treated
- Testing for HIV after pre-test information has been given
- A date for a follow-up examination when the patient is examined, results of tests, if performed, are discussed, and education is reinforced

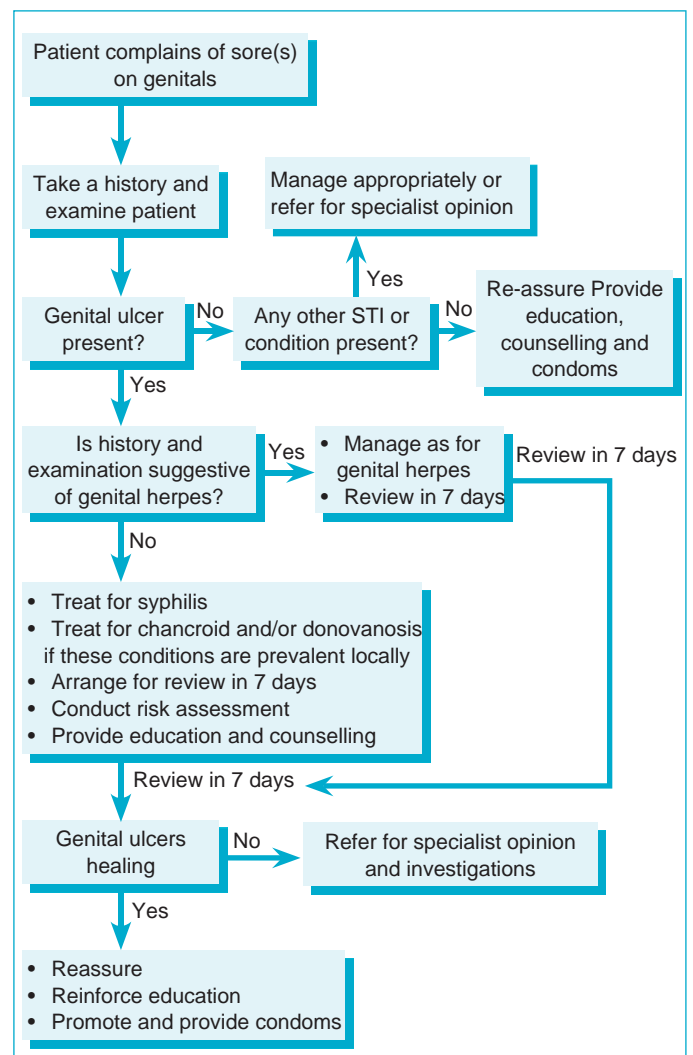

**Fig. 52.1:** Algorithm for the diagnosis and management of urethral discharge in men.

## MANAGING STI SYNDROMES

Simple clinical management flowcharts may be used to guide healthcare providers in managing patients with STI syndromes. Figures 52.1 and 52.2 are examples of clinical management algorithms for two common STI-related syndromes, urethral discharge in men, and genital ulcers in men and women.

Similar clinical management algorithms have been developed for most STI-related syndromes; however, one common syndrome, vaginal discharge in women, is quite complex and needs to be adapted locally in response to local prevalence of infections that cause vaginal discharge. Vaginal discharge may be physiologic or pathologic. Physiologic vaginal discharge is a normal state and does not require treatment. It appears at various times during the menstrual cycle, before, during, and after sexual intercourse, and during pregnancy and lactation. Therefore all women should be carefully evaluated if they present with a vaginal discharge. An abnormal or pathologic vaginal discharge may be caused by vaginitis, cervicitis and infection of the genital tract above the

**Fig. 52.2:** Algorithm for the diagnosis and management of genital ulcer syndrome in men and women.

cervix, that is, pelvic inflammatory disease (PID). In women with symptomatic vaginal discharge it is important to attempt to distinguish whether the patient has vaginitis or cervicitis. From the clinical examination alone it may not be possible to differentiate between these. Vaginitis is generally caused by trichomoniasis, candidiasis and bacterial vaginosis; though other, less common, causes of vaginitis should be kept in mind. Cervicitis is caused by gonococcal or chlamydial infection and other STIs such as genital herpes, genital warts and other cervical lesions. Developing syndromic protocols for management of vaginal discharge that are sensitive and specific for STIs in a range of settings has proven more difficult.

The World Health Organization (WHO) advises that in women with vaginal discharge a rapid behavioral and demographic screen should be carried out and has identified certain factors that are predictive for cervicitis.<sup>7</sup> These risk factors are:

- The partner has an STI
- The patient is aged less than 21 years
- The patient is not married
- The patient has had sexual contact with a new partner in the last 3 months
- The patient has had sexual contact with more than one partner in the last 3 months

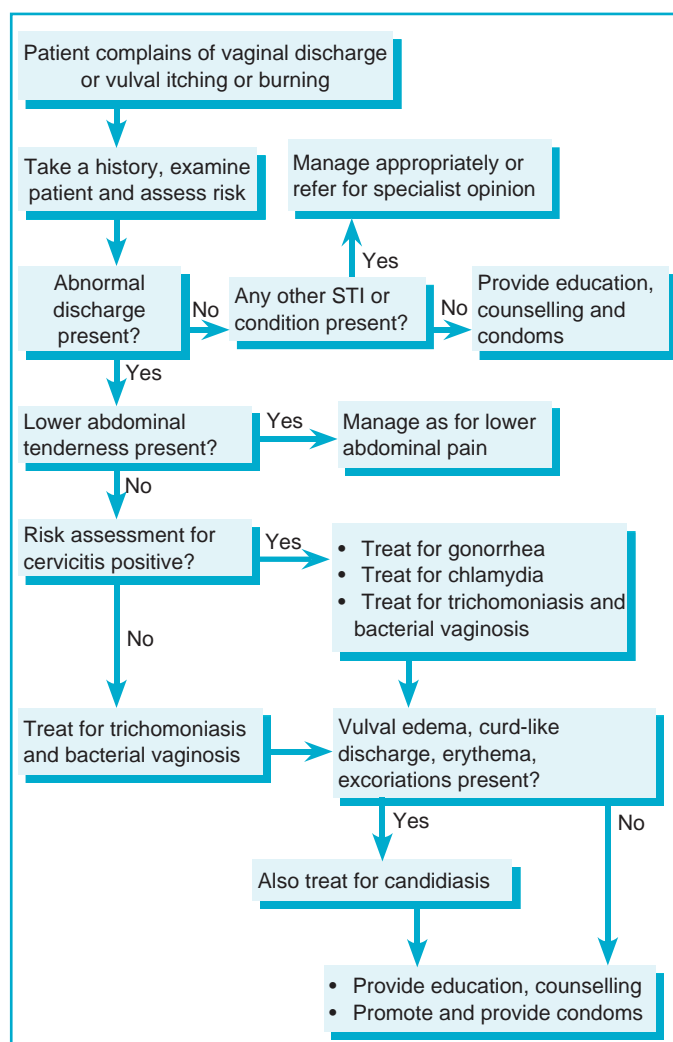

WHO advises that a woman with vaginal discharge has a positive risk assessment for cervicitis if she states that her partner is symptomatic or if she has any two of the other risks listed. An algorithm for the diagnosis and management of vaginal discharge based on risk assessment is shown in Figure 52.3.

Syndromic management algorithms for managing vaginal discharge when it is possible to carry out simple laboratory tests have also been developed<sup>3</sup> and WHO has also developed algorithms for use when a speculum examination is possible. A clinical management algorithm for the management of lower abdominal pain and tenderness is shown in Figure 52.4. It should be noted that lower abdominal pain in women may indicate a serious, life-threatening illness and in making recommendations for the management of women with such symptoms and signs causes such as acute appendicitis, ectopic pregnancy and complications of pregnancy should be addressed.

In men and women presenting with discharge dual treatment for gonorrhea and chlamydia is now widely recommended since affordable single-dose therapy with minimal side effects is available to treat both infections adequately and also because the two infections often co-exist. Syndromic management protocols will vary according to local patterns of infection and antibiotic susceptibility of microorganisms responsible for the symptoms and signs.

### Management of Urethral Discharge in Men

Common causes of urethral discharge in men include *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. In the syndromic

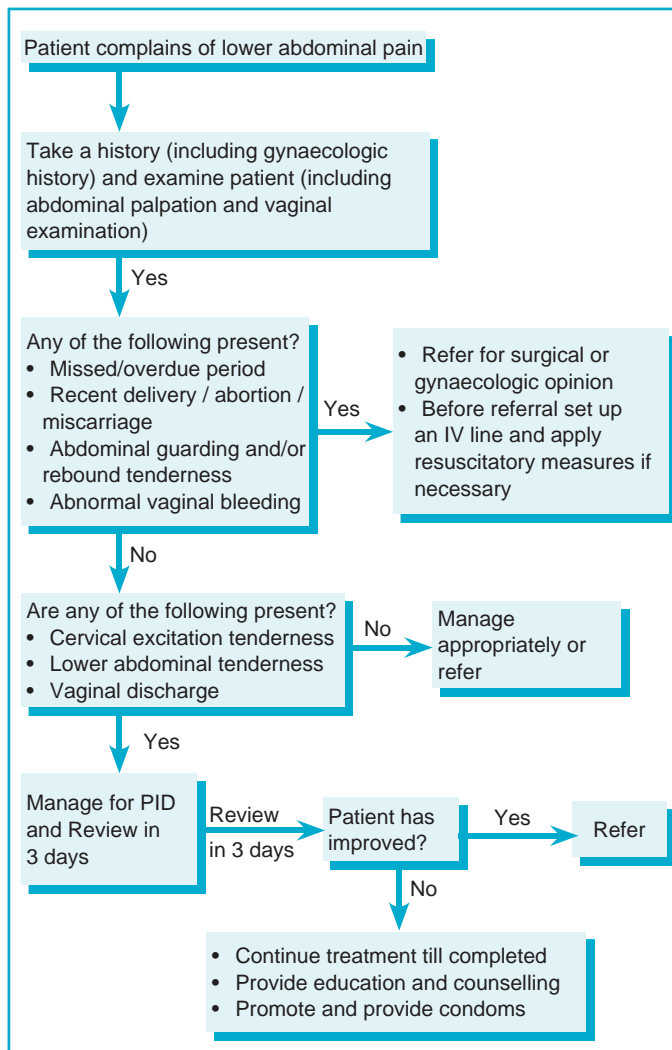

**Fig. 52.3:** Algorithm for the diagnosis and management of vaginal discharge in women.

management of men with urethral discharge, treatment should adequately cover these two organisms. A history should be taken, and the patient should be examined to determine whether urethral discharge is present or whether there is any other STI. If urethral discharge is found then the patient should be treated for gonorrhea and chlamydia. If any other STI is found the patient should be treated appropriately.

For treatment of individual infections please refer to Chapter 54.

### Management of Persistent or Recurrent Urethral Discharge in Men

Urethral discharge in men may persist or recur. If a person has been treated adequately for urethral discharge and presents with a recurrence or persistent discharge the reasons may be that he has become re-infected, he has not taken his treatment as prescribed, he has a resistant infection, or that the cause

**Fig. 52.4:** Algorithm for the diagnosis and management of lower abdominal pain and tenderness in women.

of the infection may not have been gonococcal or chlamydial infection. Men with recurrent or persistent symptoms should be examined to confirm that they do have a discharge. If a urethral discharge is present the patient should be re-treated if it is likely that re-infection or poor treatment compliance has occurred or given treatment for trichomoniasis if re-infection is unlikely and treatment compliance has been adequate. At this point it is worthwhile to take urethral specimens for laboratory examination.

### Management of Vaginal Discharge in Women

Women presenting with a history of vaginal discharge should have a history taken, a risk assessment for cervicitis carried out, and should also be examined. If it is possible a speculum examination should be performed. A spontaneous complaint of abnormal vaginal discharge, that is, abnormal in terms of quantity, color or odor, is most commonly due to a vaginal infection. Rarely, it may be the result of mucopurulent STI-

related cervicitis. *Trichomonas vaginalis*, *Candida albicans* and bacterial vaginosis are the commonest causes of vaginal infection while *N. gonorrhoeae* and *C. trachomatis* cause cervical infection. The clinical detection of cervical infection is difficult because of the asymptomatic nature of gonococcal or chlamydial cervical infection. The symptom of abnormal vaginal discharge is highly indicative of vaginal infection, but poorly predictive for cervical infection.<sup>3</sup> The WHO recommends that all women presenting with vaginal discharge should receive treatment for trichomoniasis and bacterial vaginosis, in addition those women who have a positive risk assessment for cervicitis should be treated for gonococcal and chlamydial infection as well. In women with vaginal discharge, if there is vulval edema, a curd-like discharge, vulval excoriations or erythema, treatment for candidiasis should also be given.

### Management of Genital Ulcers in Men and Women

The prevalence of pathogens responsible for genital ulcer disease varies considerably according to the geographic region. The clinical differentiation of cause of genital ulcers is inaccurate, hence management of genital ulcers is based on an understanding of the epidemiology and etiology of genital ulcers locally and recommendations should be based on local patterns of disease prevalence. In areas where both syphilis and chancroid are prevalent, it is advisable to treat all patients with genital ulcers for both conditions initially. In areas where granuloma inguinale is also prevalent, treatment for this condition should be included. In many parts of the world, genital herpes simplex virus infection has become the commonest cause of genital ulcers especially in areas where HIV prevalence is high. A number of studies have shown the benefits of adding herpes virus treatment when treating patients for genital ulcer disease. This form of episodic treatment of herpes simplex virus infection relieves the symptoms and promotes healing of lesions, thereby shortening the duration of the episode.

### Management of PID

PID is caused by infection ascending from the lower genital tract and organisms responsible include *N. gonorrhoeae*, *C. trachomatis*, and anaerobic bacteria. PID implies endometritis, salpingitis, oophoritis, and pelvic peritonitis. Women with PID have lower abdominal pain, vaginal discharge, irregular menstruation, dyspareunia, and may have fever and diarrhea. On examination there is tenderness on palpation of the lower abdomen and pelvis and digital vaginal examination will reveal cervical excitation tenderness and vaginal discharge.

Women with lower abdominal pain and/or tenderness should be examined carefully to exclude surgical or gynecologic conditions requiring immediate referral for specialist care. If the patient needs to be resuscitated then resuscitator measures should be applied before transfer and an intravenous line should be set

up. The following women with lower abdominal pain and/or tenderness should be referred for specialist opinion:

- the diagnosis is uncertain;
- surgical emergencies such as appendicitis and ectopic pregnancy cannot be excluded;
- there is a history of recent abortion, miscarriage or delivery;
- there is abdominal guarding and rebound tenderness or a mass in the pelvis suggesting pelvic peritonitis or a pelvic abscess;
- severe illness precludes management on an outpatient basis;
- the patient is pregnant;
- the patient is unable to follow or tolerate an outpatient regimen; or
- the patient has failed to respond to outpatient therapy.

Women who have acute PID and are not in any of the above categories should receive treatment for gonococcal, chlamydial, and anaerobic bacterial infection.

### Management of Acute Scrotal Swelling

Acute epididymo-orchitis should be suspected in all men presenting with acute scrotal swelling and pain. However other causes, including surgical emergencies such as testicular torsion, traumatic hematocele, and irreducible or strangulated inguinal herniae, should be excluded through careful history taking and examination. In men with acute epididymo-orchitis treatment for gonorrhea and chlamydial infection should be given. As acute epididymo-orchitis may occur as a result of bacterial infection of the urinary tract some experts believe that persons over the age of 49 years should first receive treatment for urinary tract infection as well.

### Management of Suppurative Inguinal Lymphadenitis (Bubo)

Inguinal and femoral buboes are enlargements of the lymph nodes in the inguinal regions and the femoral triangles of the body. They are caused by inflammation of lymph nodes and may lead to the formation of unilocular or multilocular abscesses. Buboes are frequently associated with lymphogranuloma venereum and chancroid. However buboes may occur in non-STIs as well, including infected lesions on the lower extremities and in some systemic infections as well. Patients with buboes should be treated for chancroid and lymphogranuloma venereum and if genital ulcers are present for syphilis as well.

### Management of Sexually Transmitted Anorectal Infections

Anorectal symptoms including anal discharge and pain are frequently encountered in men who have sex with men and in female sex workers. Gonorrhea, chlamydia, herpes simplex virus infection, and syphilis are the common causes of anorectal STIs. Symptoms associated with anorectal STIs include rectal and anal

pain, pruritus, anal discharge, anal bleeding, sensation of rectal fullness, and tenesmus, constipation, and mucous streaking of the stools. Patients with such symptoms should be carefully examined and should have anoscopy or proctoscopy performed. A high index of suspicion is needed when managing patients who have had receptive anal sex.

Patients with such symptoms should be treated for gonorrhea and chlamydial infection and if they have a genital ulcer or anal pain they should receive in addition treatment for syphilis and herpes simplex virus infection.<sup>8–10</sup>

### PROVISION OF COMPREHENSIVE STI CARE

The simple provision of antibiotics for an STI is not sufficient. The STI consultation provides an ideal opportunity to institute interventions to prevent the future acquisition of infection and to prevent further transmission. The patient-clinician encounter should be used as an opportunity to provide education on the nature of infection, and its mode of transmission and possible complications. In addition, during the encounter the patient's perception of risk and reasons for engaging in unsafe activity should be assessed and then the patient should be counseled on risk reduction. The patient should also be educated on the correct use of condoms, and the association between STIs and HIV infection. Finally, the patient should be educated on how to prevent becoming infected in future through modifying sexual behavior, that is, sexual abstinence, having sex only with a mutually faithful lifelong partner, or using condoms. It is important to bear in mind that patients with STI have put themselves at risk of becoming infected with HIV as well. The time of the consultation is an opportune moment to offer health education.

The components of comprehensive STI care are as summarized below:

- Making a diagnosis of STI after taking a history and carrying out a physical examination
- Providing antibiotics for the STI syndrome and educating the patient on the importance of treatment compliance
- Providing education on the nature of infection, possible complications, modes of transmission and prevention, and association between STIs and HIV infection
- Education on the correct use of condoms and providing the patient with condoms
- Assessing the reasons for risk taking behavior and providing counselling on risk reduction
- Education on the importance of abstaining from sexual activity until cured
- Education on the importance of attending for a follow-up examination and providing the patient with a date for follow-up attendance
- Educating on the importance of having all contacts examined and treated and initiating partner notification and contact tracing activities

## PROVISION OF EDUCATION

As part of syndromic case management all patients with STIs and those in whom the diagnosis of STI is considered should receive education on the prevention of STIs. The following education messages should be delivered during the consultation:

### Modes of Transmission of STIs and the Nature of Infection

Patients with STI should understand that infection is acquired through unprotected sexual intercourse and that there are ways to prevent becoming infected in future. These include abstaining from sex, engaging in sex with a faithful partner or using condoms when having sex.

The nature of the infection and the possible complications should also be explained. Patients should understand the seriousness of STIs. It has been established that HIV infection, the causal agent of AIDS, is an STI and is acquired in the same way as other STIs. Hence persons who engage in unprotected sex can easily become infected with HIV. Patients should also be informed that all STIs facilitate the transmission of HIV. Patients should be made aware of the fact that some STIs can cause permanent and irreversible complications such as infertility in men and women, ectopic pregnancy and serious intra-abdominal infection in women, fetal infections and blindness in neonates.

### Adherence to Treatment and Follow-up Examination

The importance of adhering to treatment and completing the full course of treatment should be emphasized. Patients should be made to understand that failure to comply with treatment may lead to complications and a reduced response to re-treatment as drug resistance may develop. Patients should refrain from sexual activity altogether while taking treatment and until they are cured. All patients should be encouraged to attend for a follow-up examination when results of tests are discussed and education is reinforced.

### Condom Promotion and Provision

Patients, males and females, should be educated on the correct use of condoms. A demonstration of the correct use of a condom should be carried out using a penis model. Patients should also be told of how to hygienically dispose of used condoms. Female condoms are now available for women to use and these allow the woman to protect herself especially when her male partner is reluctant to use a male condom. Patients should be provided with a supply of condoms at the time of the consultation and should be advised where condoms can be obtained in future.

## Partner Notification and Treatment

Provide education on the importance of partner notification and treatment. The patient should understand that in order to break the cycle of STI transmission and preventing re-infection it is important to treat not only the index presenting with infection but also the source contact and any secondary contacts that the patient may have infected after acquiring the infection. Patients should understand that many STIs remain in the body without producing any symptoms and that infected persons often do not know that they have an infection until a contact informs them. In order to reach contacts the full cooperation of the index patient is necessary. Different methods of partner treatment have been developed. Partner notification may be index patient facilitated or provider facilitated. Patient facilitated partner notification is an exercise in which the patient informs his/her partner(s) to seek care. In this method the index is provided with contact tracing cards which he/she passes on to the partners. In the provider facilitated method details of contacts are obtained from the index and then the health services seeks out the contacts. This latter method is resource intensive and is often used for a limited number of the more serious infections. Currently patient delivered partner treatment is being evaluated. In this method the index is provided with treatment for the partner and is left to his/her own resources to give the partner the treatment.

The success of partner notification and treatment programs depends on the trust and confidence that the patient has in the health service. It cannot be over-emphasized that persons with STIs are treated with respect and that healthcare provider attitudes are non-moralizing and non-judgmental and that confidentiality and privacy are assured at all times. The system of partner referral and treatment that is used depends on the setting, the resources available, and the level of prevalence of infection in a specific community.

### ASSESSING THE PATIENT'S PERCEPTION OF RISK

In order to modify sexual behavior it is necessary to assess the factors that led the patient to engage in risk-taking activity. Factors commonly associated with risky sexual behavior include, separation from the marital partner, travel away from home, economic needs, alcohol and drug use, and peer pressure. Once the possible reasons for unsafe behavior have been determined then the patient may be counseled on ways of coping with such situations. In order to modify sexual behavior it is important to find out whether the patient perceives himself/herself to be at risk of infection. Patients who engage in casual unprotected sex should be encouraged to attend for care if any of the factors listed above apply to them. The asymptomatic nature of STIs should also be explained to patients.

## PROVISION OF ACCESSIBLE AND ACCEPTABLE CARE

High-quality, effective, and acceptable STI care should be available at all health facilities in the private and public sectors and healthcare facilities providing STI care should be accessible to care seekers. The provision of STI care through categoric STI clinics is at times considered unacceptable as STI care seekers feel stigmatized and fear being identified by the public. This results in the patient seeking care elsewhere. An advantage of having categoric STI clinics is that specially trained personnel and laboratory testing facilities can be made available at the centre and hence all the needs of the care seeker can be met. In order to avoid stigmatization, persons with STIs prefer to attend facilities where they feel that privacy and confidentiality will be maintained and where they will be treated like any other healthcare seeker.

STI care is considered acceptable if the care provided is effective in relieving symptoms, preventing complications from occurring, and the care is provided in a non-judgmental and non-moralizing manner without any form of discrimination. It is ideal, therefore, to ensure that all health centers are capable of providing high quality, acceptable care for persons with STIs. Healthcare providers often feel that they are unable to provide adequate care for persons with STIs as they do not have the expertise or the laboratory facilities to make a diagnosis of STI. This is essentially true as making a diagnosis based on finding the etiologic agent causing the infection requires sophisticated laboratory tests and these will not be available at most health centers. Fortunately, however, it is not necessary, in most cases, to make a laboratory-based etiologic diagnosis before providing effective care. High-quality, effective STI care may be provided at all health facilities without the need to make a laboratory diagnosis. This may be achieved through the syndromic case management approach.

Persons with STIs often do not seek care as they feel that they may be stigmatized and discriminated against at health facilities. All health facilities should provide care for persons with STIs that is both accessible (i.e., affordable, within easy reach from home or workplace, and available at times convenient for the patient), and, acceptable (i.e., effective, non-stigmatizing, and non-discriminating).

## Summary

The syndromic case management of persons with STIs is a useful and practical way to provide high quality, effective and acceptable care for persons with STIs. Such care should be available at all health facilities. The provision of STI care should be integrated within primary healthcare facilities, maternal and child health facilities and family planning clinics. There is a need to train all healthcare providers in the syndromic case management approach. The training should be incorporated in the training curricula of medical students and basic and post basic nurses. Studies need to be carried out on a regular basis in order to monitor the antimicrobial susceptibility of etiologic agents and the change in the pattern of prevalence of STIs. Studies also need to be carried out to determine the demographic and behavioral risk factors associated with STIs.

## Genital Ulcer-Adenopathy Syndrome

Francis Ndowa • Fatim Cham • Sibongile Dlodlu

### Introduction

Genital ulcer-adenopathy syndrome is generally a presentation of some sexually transmitted infections and rarely few other dermatological/systemic conditions. Five important sexually transmitted pathogens cause the syndrome of genital ulcer disease (GUD), namely, *Treponema pallidum* (causing syphilis), *Haemophilus ducreyi* (causing chancroid), *Chlamydia trachomatis* strains L1-L3 (causing lymphogranuloma venereum), *Klebsiella granulomatis* (causing donovanosis), and herpes simplex virus type 2 (causing genital herpes). Since the prevalence of these pathogens varies by geographical settings and their epidemiology changes over time, it cannot be emphasized enough that any treatment protocol needs to respond to the locally prevailing epidemiology and the antimicrobial susceptibility patterns of the organisms. Definitive laboratory-based etiological diagnosis will require substantial financial and human resources which are not available in many situations. Additionally, even with syphilis, for which a laboratory test is the cheapest and simplest to perform, about 30% of patients will have a non-reactive non-treponemal test in early primary syphilis, i.e., the stage of the ulcer.<sup>1</sup> Furthermore, a reactive syphilis serology test does not necessarily mean that the etiology of the current ulcer is *T. pallidum*, especially in settings where there is a high prevalence of false-positive syphilis serology in the general population due to other diseases caused by spirochaetes, viz. yaws and pinta.

The common practice of a physician's clinical diagnosis of GUD has been shown to be inaccurate in a number of studies. The inaccuracy is due to a number of factors, including mixed infections, atypical appearance or simply similarities in appearance between ulcers caused by one or the other pathogen. Studies undertaken in Johannesburg, South Africa, demonstrated an accuracy of 55% for syphilis and 22% for genital herpes based on a clinical diagnosis. In another study using PCR techniques, syphilis and genital herpes were both under-diagnosed giving a clinical diagnosis sensitivity of 31% and 47%, respectively, whereas syndromic management protocols provided adequate treatment for 90% of patients with GUD in that setting.<sup>2-4</sup> Therefore, in the

absence of a cheap, reliable multiplex test for GUD, syndromic management seems to offer the next best option. This approach works equally well for men and women with ulcerative disease. In much the same manner as for urethritis in men, WHO has recommended the syndromic management protocols for GUD in both men and women.

### Epidemiology of Genital Ulcers

The relative prevalence of sexually transmitted pathogens that cause genital ulcers varies widely from country to country and within countries. Thus, it is important to conduct etiological studies to determine what the prevailing pathogens in a particular country of setting are. Table 53.1 shows some data collected from different geographic regions between 1998 and 2010 using molecular diagnostic tests, which are more sensitive and, in many cases, more specific than conventional laboratory methods for the detection of sexually transmitted infections.<sup>5,6</sup> The diagnosis of donovanosis and LGV, however, is usually made from clinical appearance, and there may be considerable under-reporting of these infections.

### Genital Herpes

Genital herpes caused by herpes simplex virus (HSV) type 1 or 2 is the most common cause of GUD globally and is a cofactor in HIV acquisition and transmission. The incidence of genital herpes is on the rise in most countries, and in many countries it has become the most common cause of genital ulceration. The majority of patients infected with HSV type 1 or 2, may not be aware of their infection because the infection is either asymptomatic or sub-clinical or unrecognized. Since asymptomatic or sub-clinical genital viral shedding can occur, HSV infection may be transmitted unknowingly to sexual partners.

### PATHOGENESIS

HSV infection occurs when viral particles enter the skin or mucous membranes through microscopic abrasions. Entry of

**Table 53.1:** Etiology of Genital Ulcers in Various Countries<sup>7–18</sup>

\*Disease not included in evaluation.

the virus is mediated by attachment of the viral envelope to the cell surface receptor (heparin sulfate). This fusion allows the de-enveloped virus capsid to be transported to the nuclear pores and release of viral DNA into the cell. The immediate early (IE) or alpha genes of the virus initiate the replication and then activate the early or beta genes. The beta gene produces enzymes necessary for viral replication, such as HSV thymidine kinase and the replication proteins. Gamma genes are the last to be expressed, and these genes code for structural proteins. Assembly of the herpes virus nucleocapsids begins in the nucleus. The replicative efficiency of HSV is poor, as the ratio of infectious to incomplete virions is low.

Once replication establishes inside the cell's nucleus, virus spreads to surrounding cells, damaging epidermal and dermal layers. The virus then enters peripheral sensory or autonomic nerve endings and migrates to the nerve root ganglia. Once in the ganglia the virus establishes a lifelong, latent infection from which periodic reactivation and replication occur. With reactivation, the virus descends from the ganglia and nerve root to the genital mucosa or skin. These reactivation processes classically cause genital ulcers, but asymptomatic reactivation is common.

## CLINICAL FEATURES

First episode of HSV infections occurs in those people without a previous history of genital herpes. The first episode may be primary, in which the affected person is seronegative for HSV antibodies, or it may be non-primary or first recognized recurrence in a person with serologic evidence of previous infection. A primary episode of HSV infection occurs after an incubation period of about 4 days, with a range of 2–12 days. Characteristically, the lesions arise

as multiple, painful, small, grouped vesicles on an erythematous base. These vesicles soon rupture to form erosions and shallow ulcers. The other features include edema of the external genitalia and tender, non-fluctuant inguinal lymphadenopathy. Without treatment the first episode lasts 3–4 weeks. Recurrent episodes are less severe and last 5–10 days only.

## DIAGNOSIS

In the majority of settings, the diagnosis of genital herpes is made clinically based on the characteristic grouped vesicles with an erythematous base. However, other conditions such as chancroid, syphilis, and contact dermatitis may present in a similar manner. Clinical diagnosis of genital herpes is poor even in experienced clinicians as was demonstrated in a study that showed that only about 40% of new genital herpes infections are diagnosed correctly on clinical suspicion.<sup>19</sup> Detection of HSV DNA from lesional samples by polymerase chain reaction is the most sensitive and specific method at present. Other methods include cell culture or antigen detection by immunofluorescence. Type-specific serologic tests for HSV 1 and HSV 2 may also be used, especially for patients from whom lesional samples cannot be obtained.

## TREATMENT

The recommended regimen for primary episode includes acyclovir, 400 mg three times a day or 200 mg five times a day for 7–10 days. Alternatively, famciclovir can be given in a dose of 250 mg three times a day or valacyclovir, 1 g twice daily for 7–10 days. Recurrent episodes can be treated with acyclovir in the

same doses as mentioned above, but only for 5 days. Alternate regimens include famciclovir in a dose of 125 mg two times a day for 5 days or valacyclovir 500 mg twice daily for 3–5 days.

## Syphilis

Although the incidence of syphilis has declined steadily for most of the twentieth century in Western Europe and North America, it is still an important infection in developing countries. The etiologic agent is a spirochete, *Treponema pallidum* (*T. pallidum*), a spiral structure visible by light microscopy only under dark-field illumination, and it cannot be grown on artificial growth media. In tissue culture and in animal models it divides slowly, with a replication time of approximately 30 hours. Transmission by sexual contact requires contact with moist mucosal or cutaneous lesions. *T. pallidum* cannot be distinguished in the laboratory from the agents responsible for yaws and pinta (*T. pertenue* and *T. carateum*, respectively). The organism is highly susceptible to drying.

## PATHOGENESIS

*T. pallidum* has not been shown to produce either exotoxins or endotoxins. Following experimental infection in the rabbit, *T. pallidum* begins to replicate once it has passed through the epithelium. An initial polymorphonuclear leukocyte response is soon replaced by an infiltrate of T and B lymphocytes. The primary chancre also contains mucoid material, mainly hyaluronic acid and chondroitin sulfate, which may modulate the host immune response. Secondary lesions appear in a certain proportion of infected persons some weeks after the primary infection. Much of the pathology of these secondary manifestations of syphilis may be immune complex mediated. High levels of antitreponemal antibody are present in the circulation, but cell-mediated immune responses are depressed. Without adequate treatment the organism can survive in the body for many years and may lead to tertiary syphilitic lesions characterized by the presence of a small number of organisms and a lymphocytic host response giving rise to endarteritis.

## CLINICAL FEATURES

After incubation period of 9–90 days (median 21 days), an ulcer, known as a chancre of primary syphilis, develops at the site of inoculation. Typically, the chancre is a single painless, indurated lesion with a raised edge. In men it is most commonly on glans penis, the foreskin, the coronal sulcus, or the shaft of the penis and in women on the cervix or vulva. The chancre does not bleed on contact. It is often accompanied by inguinal lymphadenopathy with the enlarged glands being characteristically firm, discrete, slippery, and painless. Without treatment the chancre characteristically resolves over 2–6 weeks. Secondary manifestations of syphilis appear generally between 3 and 6 weeks after the first appearance of the chancre. Secondary syphilis is usually recognized by the appearance of a non-itchy skin rash

that may be papular, macular or rarely pustular in nature. In moist areas of the body (e.g., perineum and axilla) the papules may become soft raised lesions known as condylomata lata. These lesions, teeming with spirochetes, are highly infectious. The rash may also be seen on the palms and soles. Mucous membranes may be involved with mucous patches or oral ulceration, sometimes in the form of the characteristic “snail track” ulcer. In addition to its cutaneous manifestations, secondary syphilis may cause systemic illness, giving rise to fever, malaise, generalized lymphadenopathy, nephritis, hepatitis, meningitis, or uveitis.

The lesions of primary and secondary syphilis generally resolve spontaneously after several weeks. If not treated, or inadequately treated, the patient then enters the latent stage of the disease and is likely to develop tertiary syphilis at some time in the future. The lesions of tertiary syphilis fall into three categories: the gumma, cardiovascular disease, and central nervous system disease. The classic Oslo study of untreated syphilis, in which some 1400 patients were followed up for up to 50 years, found that the most common late manifestation was the gumma, a painless “punched out” ulcer with little or no inflammatory reaction, which developed in 15% of the patients. Most of the lesions were cutaneous (about 70%) and 10% involved bone. Most cases occurred in the first 15 years following infection. Cardiovascular lesions (aortitis, aortic valve disease or coronary ostial occlusion) were seen in 15% of men and 8% of women, with onset typically 30–40 years after infection. Neurological manifestations were seen in 9% of men and 5% of women, with meningovascular disease typically occurring after 15–20 years and tabes dorsalis or general paresis after 20–30 years.<sup>20</sup> A detailed account of syphilis and its manifestations are given in a separate chapter.

## DIAGNOSIS

The most specific diagnostic method of early syphilis is identification of the spirochete under dark-field microscopy in exudate from the ulcer, condylomata lata or lymph node aspirate. Other direct diagnostic methods are direct fluorescent antibody test for *T. pallidum* (DFA-TP) or polymerase chain reaction (PCR). Serologic tests are used as indirect methods of diagnosing syphilis using non-treponemal tests such as the rapid plasma reagin test (RPR) or treponemal tests such as the fluorescent treponemal antibody absorption (FTA-ABS) test, the *T. pallidum* passive particle agglutination assay (TP-PA) or the *T. pallidum* hemagglutination assay (TPHA). More recently, a number of immunochromatographic strip tests have been developed as rapid point-of-care tests for syphilis screening using either serum or whole blood.

## TREATMENT

Penicillin remains the mainstay of treatment for syphilis since confirmation of its effectiveness in 1943. There have been no reports of *T. pallidum* developing resistance against penicillin. Single intramuscular injection of 2.4 million (1.2 million in each buttock) units of benzathine penicillin is the treatment of

choice. In patients allergic to penicillin, desensitisation should be attempted. If that is not possible, alternative treatment regimens like doxycycline 100 mg twice daily, or erythromycin 500 mg four times daily, for 2 weeks for early syphilis and for 1 month in cases of late syphilis can be given.

## Chancroid

Chancroid is caused by the bacterium *Haemophilus ducreyi*, a small facultative anaerobic gram-negative bacillus, endemic in settings with poor access to health services such as Africa, Asia and South America, and the Caribbean. Although generally rare in industrialized countries, there have been several well-documented outbreaks in North America since the 1970s. Characteristic features of these outbreaks have been a high male-to-female case ratio, the involvement of sex workers and the low socioeconomic status of the populations affected. A study in Nairobi investigated the role of asymptomatic females in the transmission of the disease and concluded that they were of little importance.<sup>21</sup> Studies among Australian soldiers during the Vietnam war suggest that chancroid is more common among uncircumcised than circumcised men.<sup>22</sup> In the era of the human immunodeficiency virus (HIV) and AIDS, chancroid is of particular importance as prospective studies among both males and females at high risk of HIV infection have suggested that it significantly increases the risk of transmission of HIV via heterosexual contact, by increasing infectivity, susceptibility or both.<sup>23,24</sup>

## PATHOGENESIS

Histopathologically, chancroid ulcers contain three distinct zones, namely, a superficial zone of necrotic tissue, fibrin and numerous bacteria, an intermediate edematous zone with new vessel formation, and a deep zone of dense infiltrate of neutrophils and plasma cells with fibroblastic proliferation. The inguinal lymphadenopathy is paucibacillary but with a large number of neutrophils.

## CLINICAL FEATURES

After infection, a papule appears at the site of infection after about 3 days, with an incubation period that ranges from 1 to 7 days. The papule quickly ulcerates giving rise to the typical painful, soft ulcer of chancroid. Characteristically, the ulcer has a purulent base with an undermined edge and bleeds on contact. Presentation with multiple ulcers is common. Unilateral, but sometimes bilateral, painful inguinal lymphadenopathic swellings (bubo) are seen in about 30–50% of cases. Atypical presentations are, however, common, and even in experienced hands chancroid cannot reliably be distinguished from primary syphilis on clinical grounds.<sup>25</sup> Herpes simplex virus infection, LGV, and donovanosis also come into the differential diagnosis of chancroid. Chancroid may cause rapid, extensive local destruction of the genitals, particularly in HIV-infected individuals.

## DIAGNOSIS

Gram-stained smears obtained from ulcers lack both sensitivity and specificity for the diagnosis of chancroid. Isolation of *H. ducreyi* from the ulcer provides a definitive diagnosis, but this is a laborious process. To obtain adequate material, swabs should be taken from the ulcer base (invasive and extremely uncomfortable for the patient) and plated directly on appropriate blood-containing media enriched with fetal calf serum and Vitox and made selective with vancomycin. For optimal rates of isolation, media made up from both GC agar and Mueller–Hinton agar base should be inoculated. Plates should be incubated for at least 72 hours in an atmosphere of 5% carbon dioxide at 33°C. This requires both high-quality laboratory equipment and highly trained staff.

## TREATMENT

Chancroid ulcers should be kept clean and dry with regular washing with soap and water. For a number of years, sulfamethoxazole-trimethoprim (cotrimoxazole) or erythromycin in standard dosage given by mouth for 7 days have been the effective therapy, but *H. ducreyi* isolates have acquired plasmid-mediated resistance to sulfonamides. Since hardly any studies have been conducted recently, the current prevalence and distribution of anti-microbial resistance in *H. ducreyi* is not known, but macrolides, quinolones, and cephalosporins, such as ceftriaxone are still effective against *H. ducreyi*. Ciprofloxacin, 500 mg daily for 3 days by mouth, ceftriaxone, 250 mg as a single intramuscular dose or azithromycin 1 g orally in a single dose appear to be effective treatment regimens.

## Lymphogranuloma Venereum

The epidemiology of lymphogranuloma venereum (LGV) is not well-defined because of lack of a sensitive and specific diagnostic test for its detection. LGV is largely confined to the tropics and in most places it accounts for only a small proportion of patients with STIs. The disease is seen more often in men than women, though the late anorectal complications are more prevalent in women.

## ETIOLOGY AND PATHOGENESIS

Lymphogranuloma venereum is caused by the invasive L1, L2, and L3 strains of *Chlamydia trachomatis*. Characteristically, the pathological features are a transient, herpetiform primary ulcer of the external genitalia. In many cases, however, the primary lesion is not noticed by the patient on account of lack of symptoms or being internal on the cervix in women. Most patients seek healthcare when the lymphatic system becomes infected. Such infections eventually lead to thrombolympangitis and perilymphangitis with proliferation of the endothelial cells of the lymphatics. In the lymph nodes, prominent migration of neutrophils leads to characteristic abscess formation seen in the inguinal and femoral glands.

## CLINICAL FEATURES

The small ulcer of LGV is so evanescent that most patients miss it. However, in men who have sex with men genital ulceration and inguinal syndrome may be present at the same time.<sup>26</sup> Patients usually present at the “bubo” stage. Thus, when a sexually active adult presents with an inguinal bubo not associated with genital ulcer, LGV should be suspected. The incubation period ranges from 3 to 30 days. If recognized the presentation is typically a small, self-limiting, painless ulcer on the genitalia. The second phase of the illness is the development of increasingly painful lymphangitis and lymphadenitis, accompanied by fever and malaise. The infected nodes (bilateral in one third of cases) coalesce into a matted mass. The nodes may rupture and open into multiple sinuses. Untreated, the disease may cause extensive lymphatic damage resulting in elephantiasis of the genitalia. The combination of elephantiasis with skin breakdown sometimes seen in late cases is referred to as esthiomène. In women and in men having sex with men, the disease may present as an acute proctocolitis which, in a proportion of cases, leads to abscess formation, fistulae, and rectal strictures. In the Caribbean, a high incidence of vulval carcinoma has been recorded among premenopausal women with scars of either LGV or donovanosis.<sup>27</sup>

## DIAGNOSIS

At primary health-care level, the diagnosis is mostly based on clinical examination. The diagnosis of LGV can only be confirmed in specialist centres with facilities for the isolation and identification of *C. trachomatis* L1–3 strains, or the ability to perform the micro-immunofluorescence serological test.<sup>28</sup> Other serological tests show cross-reaction with other serovars of *C. trachomatis*, and with other species of Chlamydia, such as *C. pneumoniae*. The accepted criterion for a positive diagnosis is a micro-immunofluorescence titer of 1:512. The presence of stellate abscesses in biopsy material is suggestive of LGV. Direct fluorescent antibody (DFA) staining may be used to demonstrate chlamydial elementary bodies in tissue or discharge from buboes. The process to obtain an accurate diagnosis, much as in the case of diagnosis of chancroid, is costly.

## TREATMENT

Being an infection caused by one of the chlamydia group, tetracyclines and erythromycin are effective treatments. If treatment is delayed, antibiotics are of little benefit in preventing the late sequelae of rectal stricture and elephantiasis of the genitalia. Corrective surgical procedures may be of benefit in cases with extensive elephantiasis or deformity. Any suspicious areas in healed scars should be examined for malignant change.

## Donovanosis

Donovanosis is caused by a bacterium, endemic in areas localized to a few specific parts of the tropics. The most important of these are currently the southeast India, Papua New Guinea (PNG),

Brazil, The Guyanas, and eastern parts of South Africa. The disease is strongly associated with sex work and low socioeconomic status. Outside PNG, the highest recently reported incidence of donovanosis has been in Durban, South Africa, where 16% of genital ulcers in men were due to donovanosis.<sup>29</sup>

## ETIOLOGY AND PATHOGENESIS

The disease is caused by an intracellular, encapsulated gram-negative coccobacillus, previously called *Calymmatobacterium granulomatis*. Recently the organism has been re-classified as a *Klebsiella* on the basis of ribosomal RNA sequences.<sup>30</sup> The disease primarily attacks the skin and the bacteria are carried to inguinal nodes where they occasionally cause a suppurating periadenitis (“pseudobubo”) but mostly these lesions are independent of the lymph nodes. The key histological features are epithelial hyperplasia, a dense dermal infiltrate of plasma cells and scattered large macrophages containing clusters of Donovan bodies.

## CLINICAL FEATURES

The first manifestation, appearing after 3–40 days incubation period, is usually a small papule which ruptures to form a granulomatous lesion that is characteristically pain-free, “beefy-red” in color, bleeds readily on contact and is often elevated above the level of the surrounding skin. If not treated, the ulcers gradually extend along skin folds towards the groins and the anal area. Complications include rapid extension of lesions secondarily infected with fusospirochaetal organisms, scarring, elephantiasis, and rarely the development of squamous carcinoma.

## DIAGNOSIS

The diagnosis requires the demonstration of intracellular Donovan bodies in biopsy material or smears taken from active areas and stained by Giemsa or Leishman stains.

## TREATMENT

The most widely used antibiotics are tetracyclines, chloramphenicol, cotrimoxazole, and erythromycin. Thiamphenicol, lincomycin, norfloxacin, and azithromycin have recently been shown to be of value, but studies in Australia have shown that azithromycin is the treatment of choice.<sup>31</sup> Treatment should be continued until lesions have resolved and, if possible, a little longer to reduce the risk of relapse. Corrective surgical procedures are required in some patients to ameliorate deformities from scarring. Treatment of sexual partners who do not have lesions is not thought necessary.

## Non-venereal Causes of Genital Ulcer

Non-venereal ulcers in men and women are commonly seen in genitourinary clinics. Genitalia may be traumatized and develop minor erosions and ulcerations even during normal sexual activity, more often with sexual aids (sexual toys), the practice of dry sex or vigorous sex under the influence of drugs.

In research settings, 12–50% of genital ulcers have no defined etiology, even with modern molecular diagnostic methods.<sup>8,14,15</sup>

Many dermatological or systemic and blistering disorders can cause ulceration of the genitalia in both sexes. In a descriptive, observational study conducted in Brazil in 2005 among women approximately 55% of the ulcers were due to a sexually transmitted pathogen, predominantly herpes simplex virus (53%) and about 2% were syphilitic ulcers. In the remaining 45% of the cases, the ulcers were non-sexually transmitted. Some of the identified causes of the latter were Behçet disease, hidradenitis suppurativa, ulcerative lichen sclerosis simplex, pemphigus vulgaris and vulvar intra-epithelial neoplasia (VIN) and autoimmune ulcers.<sup>32</sup> In a small study of 13 immunocompetent, non-sexually active adolescent girls in Paris, acute GUD was related to infection with the Epstein-Barr virus in 4 patients (31%), Behçet disease in 1 patient and no pathogen was identified in the rest (about 42%).<sup>33</sup>

Whatever the cause of an ulcer, it is important to be aware that the presence of an ulcer increases the risk of acquiring or transmitting HIV. Therefore, due attention and early management are essential. Some of the uncommon non-sexually related causes of GUDs are described below.

**Amoebiasis**, caused by the pathogen *Entamoeba histolytica*, is typically a disease of the colon. This is endemic in many tropical countries. Cutaneous amoebiasis may involve the genitalia.<sup>34</sup> It manifests as a well-defined, serpiginous, tender ulcer with indurated, erythematous margins. The base of the ulcer is friable and bleeds easily. There is a foul-smelling hemopurulent discharge. Regional lymph nodes are often enlarged. The ulcer may mimic syphilitic chancre, chancroid, donovanosis, and genital neoplasia. Diagnosis can be made by wet mount to visualize the parasite. Stool examination may add to the diagnosis. Treatment includes metronidazole, 400 mg three times daily for 10 days or tinidazole, 2 g once a day for 2 days.

**Behçet disease** is characterized by a triad consisting of oral aphthous ulcers, genital ulcers, and uveitis. Genital lesions begin as small asymptomatic papules or papulovesicles, which soon erode to form erythematous, painful, punched out ulcerations. The ulcers heal spontaneously over a period of time (several weeks to months), but may recur. The diagnosis is based on the presence of oral aphthae and involvement of other organ systems including the eye. Genital lesions may mimic syphilitic chancre, genital herpes, chancroid, and sometimes, when lesions are destructive, donovanosis. Extensive ulcerations should be treated with colchicine (0.5 mg three times a day), dapsone (100–200 mg/day), prednisolone (40 mg/day) or once weekly methotrexate.

**Crohn disease** is a chronic, inflammatory, granulomatous disease that primarily affects the gastrointestinal tract. Cutaneous extension of the bowel disease affects perianal and genital skin. Alternatively, metastatic Crohn disease may affect distant sites including perianal, vulval, penile, or scrotal skin. The skin lesions caused by local extension may be in the form of nodules, abscesses, sinus tracts, and fistulae. The metastatic disease is characterized by deep, punched out ulcers. The diagnosis can be confirmed by

histopathological examination of a tissue biopsy. Non-caseating granuloma in the dermis or subcutis along with epidermal erosion is characteristic. Cutaneous lesions may resolve after bowel disease improves. Treatment for Crohn disease should be done in consultation with a gastroenterologist.

**Human bites** to the genitalia are one of the rare causes of penile ulceration. Although patients tend to present late due to embarrassment, such traumatic injuries are increasingly being reported, probably due to the increasing frequency of orogenital sex. The ulcers are often contaminated with oral flora and they should be treated early with irrigation and debridement. Bite wounds to the genitalia may result in superficial tissue necrosis and deep ulceration due to the virulent human oral flora. Anti-microbial treatment is indicated provided malignant lesions have been excluded.<sup>35,36</sup> The role of prophylactic antibiotics is not clearly defined in animal bites, but there is evidence that prophylactic anti-microbial treatment is of benefit following human bites, but the data are insufficient, particularly for the genital area.<sup>37</sup>

**Fixed drug eruptions** frequently affect the glans penis and may present as genital ulcer.<sup>38</sup> A history of recent drug intake may help in the diagnosis.

## Syndromic Management of GUD

Although the literature may describe clinical appearances that are supposed to assist towards identification of causative agents for particular ulcers, practice in the field has shown that even experienced physicians make the wrong diagnosis from that. A number of laboratory diagnostic tests, which may help in the confirmation of the diagnosis of genital ulcers exist, and some are mentioned in Table 53.2. However, high-quality laboratory facilities are not available in many health-care settings and at nearly all primary health-care facilities. Therefore, depending on the relative prevalence of causative organisms for GUD and their antibiotic sensitivities, appropriate treatment combinations should be given syndromically using combinations suggested in Table 53.3. The guiding principle is shown in Fig. 53.1.

The decision to treat for any combination of the above will depend on the local epidemiology of the infections and the national treatment guidelines for sexually transmitted infections. All fluctuant buboes should be aspirated, not surgically incised, directing a large bore needle through as much normal skin as possible. Burst buboes should be cleaned and dressed with antiseptic solution or dilute saline solution until epithelialization is complete.

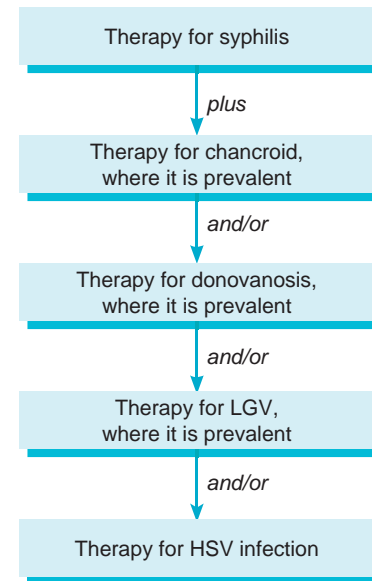

Surveillance for genital herpes should be observed in all settings as the HSV 2 seems to be predominating as the cause of GUD in both developing and developed countries.<sup>39–41</sup> Recent reports from parts of Africa, Asia, and Latin America indicate that GUD is more frequently a result of HSV 2 infections. In order to minimize overtreatment in Peru, where HSV caused 43% of genital ulcers, patients with vesicular genital lesions were excluded in syndromic management of GUD. This reduced the over-treatment rate for syphilis and chancroid from 76% to 58%, but the sensitivity for these two diseases was also reduced

**Table 53.2:** The Appropriate Specimens and Diagnostic Tests for Sexually Transmitted Microorganisms Causing Genital Ulcer-Adenopathy Syndrome

Microorganisms	Diseases	Laboratory tests	Specimens
Herpes simplex virus	Genital herpes	Tzanck smear from ulcer/vesicle	Ulcer base smear
		Cell culture, Antigen detection	Ulcer swab
		DNA tests (PCR)	Ulcer swab
		Type-specific serology	Blood
<i>T. pallidum</i>	Syphilis	Dark-field microscopy, Serology	Fluid from ulcer, Blood
<i>H. ducreyi</i>	Chancroid	Gram-stain, Culture, PCR	Ulcer swab
<i>Klebsiella granulomatis</i>	Donovanosis	Direct stain/Wright-Giemsa, Culture, PCR	Tissue biopsy
<i>C. trachomatis</i>	LGV	Cell culture, Antigen detection, PCR	Ulcer swab

from 100% to 88%.<sup>42</sup> If specific antiviral treatment of HSV 2 is not considered it will have implications on the efficacy of the syndromic management of GUD. In areas of high HIV prevalence, the clinical presentation of ulcers caused by HSV 2 is different from the classical descriptions. In such areas the management for suspected genital herpes should include specific antiviral therapy, such as acyclovir, famciclovir or valacyclovir. The GUD flowchart (Fig. 53.1) introduced by WHO in their

**Fig. 53.1:** Recommended syndromic treatment for genital ulcer disease.

revised guidelines proposes specific treatment for HSV 2 in the first-line treatment combinations for GUD.<sup>43</sup>

### EFFICACY OF SYNDROMIC MANAGEMENT FOR GENITAL ULCER-ADENOPATHY SYNDROME

A recent review showed sensitivity for the algorithm for the diagnosis and treatment of GUD in men ranging from 68% to 98%.<sup>44</sup> In China, in patients with genital ulcers, the sensitivities were 78.3% and 75.8%, specificities were 83.6% and 42.9%, and positive predictive values were 60.0% and 41.0% for the diagnosis of syphilis and genital herpes, respectively, using the syndromic

**Table 53.3:** Treatment Options that can be Combined for the Syndromic Management of GUD

Genital herpes (first episode)	Genital herpes (recurrent episode)	Syphilis	Chancroid	Donovanosis	LGV
Acyclovir, 400 mg three times a day for 7–10 days	Acyclovir, 400 mg three times a day for 5 days	Benzathine penicillin, 2.4 million units IM at a single session	Ciprofloxacin, 500 mg orally, twice daily for 3 days	Azithromycin 1 g orally on first day, then 500 mg orally once a day until lesions heal	Doxycycline, 100 mg orally, twice daily for 14 days
Acyclovir, 200 mg five times a day for 7–10 days	Acyclovir, 200 mg five times a day for 5 days	Procaine benzylpenicillin, 1.2 million units IM daily for 10 consecutive days	Erythromycin, 500 mg orally, three times daily for 7 days	Doxycycline, 100 mg orally, twice daily until lesions heal	Erythromycin, 500 mg orally, four times daily for 14 days
Famciclovir, 250 mg three times a day for 7–10 days	Famciclovir, 125 mg twice daily for 5 days	Doxycycline, 100 mg orally twice daily for 14 days	Azithromycin, 1 g orally as a single dose	Erythromycin, 500 mg orally, four times daily until lesions heal	
Valacyclovir, 1g orally twice a day for 7–10 days	Valacyclovir, 500 mg orally twice a day for 3–5 days		Ceftriaxone, 250 mg IM, as a single dose		

approach.<sup>45</sup> In a recent study from Taiwan, syndromic management was found to be a more cost effective protocol compared with the current and etiologic protocols for the management of STIs.<sup>46</sup> A study from Nigeria concluded that syndromic case management of STIs can be conveniently integrated into primary healthcare delivery system.<sup>47</sup> The syndromic approach, though simple and effective at a considerably reduced cost, has some limitations. Many patients do not fit into the pattern of a classical syndrome even when symptoms related to genitalia are present as has been brought out in a large study from central India.<sup>48</sup> However, in the majority of cases, the syndromic management protocol for genital ulcer adenopathy syndrome provide adequate treatment to more than 90% of patients with GUD; however, this is at the cost of overtreatment in a significant proportion of patients.

It should be remembered that whether a country adopts the syndromic approach or the laboratory-based etiologic approach, asymptomatic patients who remain out of the ambit of either a syndrome or a symptomatic infection will need supplementary strategies for the detection of infection. Such strategies include screening and case finding policies.

# Urethral Discharge

Francis Ndowa • Sibongile Dlodlu

54

## Introduction

Sexually transmitted infections (STIs) are caused by over 30 diverse pathogens, including bacteria, viruses, protozoal agents, fungal agents, and ectoparasites. Most STI pathogens infect the reproductive tract as their primary site. *Neisseria gonorrhoeae* (*N. gonorrhoeae*) and *Chlamydia trachomatis* (*C. trachomatis*) are the two most common sexually transmitted bacteria and commonly present with urethral discharge in men.

## Causative Pathogens and Pathogenesis

The causes of urethral discharge are classified as gonococcal and non-gonococcal. The former is the most common cause of acute urethral discharge in the African region and the south-east Asia region, whereas chlamydial infections seem to predominate in other geographic areas, particularly in Europe and North America. For example, data from men with urethral discharge attending STI clinics in Africa show the causative agent to be *N. gonorrhoeae* in more than 50% of cases and *C. trachomatis* is implicated in a range of 5–15% of cases, and dual infections are common.<sup>1,2</sup> Non-specific urethritis (NSU), after exclusion of cases of *N. gonorrhoeae* and *C. trachomatis*, accounts for about one-quarter or one-third of cases of urethral discharge. In settings where it has been investigated, *Trichomonas vaginalis* is not an infrequent pathogen, accounting for perhaps 2–20% of cases of acute urethral discharge.<sup>3</sup> Other organisms such as *Mycoplasma genitalium* and *Ureaplasma urealyticum* have been implicated, but they are difficult to demonstrate. *Candida* species can be isolated from patients with urethritis in less than 1% of cases; however, its significance is not fully understood. *Candida* urethritis is often associated with balanitis. Other rare causes include Meningococcus, group B streptococci, *Staphylococcus saprophyticus*, *Gardnerella vaginalis*, and *Corynebacterium genitalium*.

### GNOCOCCAL INFECTION

*N. gonorrhoeae*, a gram-negative diplococcus found only in humans, is especially adept at colonizing the epithelial surfaces

of the male and female urogenital tract, conjunctiva, pharynx, rectum, and synovium. Its virulence is conferred by the presence of pili that mediate adherence sufficient to withstand hydrodynamic forces within the urethra. These pili also inhibit uptake by phagocytes. No specific toxins have been described as being produced by *N. gonorrhoeae*, but the organism is highly adept at avoiding the host immune response. The pilus antigens, the protein designated as P.II, and the lipo-oligosaccharide are capable of antigenic variation sufficient to permit repeated re-infection of the same host within a short period. The mucosal immune response to infection is characterized by the production of IgA, IgM, and IgE which can inhibit adherence and facilitates opsonization, but the bacteria produce an IgA1 protease which may impair the host mucosal immune response.

The risk of contracting gonorrhea after a single exposure is about 20% for males and probably higher for females. Most men develop symptoms within 5 days of infection, with an average incubation period of 3 days. Ninety percent of men will experience symptoms within 14 days of infection. Asymptomatic infections are more frequent in women, accounting for up to 80% of infections detected in sexual partners of symptomatic patients.

### Clinical Presentation

Gonococcal infections are commonly limited to mucosal surfaces, such as the urethra, the cervix, rectum, pharynx, and conjunctiva. The prepubertal vaginal epithelium is also susceptible to infection as the vaginal epithelium will not have keratinized in young adolescent girls. Symptomatic uncomplicated gonococcal infections in men manifest typically as thick, yellow urethral discharge (Fig. 54.1). Accompanying symptoms may include metal itching, burning, dysuria, and frequency of micturition. Infections of the pharynx and rectum (mostly asymptomatic) can result from orogenital and genitoanal sexual contact in men who have sex with men, as well as in women practicing anal sex. Women can also experience rectal infection by contamination from an infected vaginal discharge.

**Fig. 54.1:** Thick, yellow urethral discharge typically seen in symptomatic uncomplicated gonococcal infection.

## Complications

In men, spread of the infection to the epididymis, usually unilateral, is the most common complication. Acute epididymitis, which occurs in up to 20% of untreated infection, has to be distinguished from acute testicular torsion, which is a surgical emergency. Certain complications of gonorrhea are now seldom encountered in industrialized countries but may still be seen in developing countries. These include abscess and fistula formation resulting from spread of infection to various glands associated with the genitourinary tract, such as the prostate gland, Tyson, Littre, and Cowper glands. Ultimately, these may lead to urethral stricture, a complication difficult to manage, which appears to show marked geographical variation in settings with poor access to health-care services.<sup>4,5</sup> In women, untreated cervical infection may lead to involvement of the pelvic organs including the endometrium, the fallopian tubes, and the pelvic peritoneum, resulting in the syndrome of pelvic inflammatory disease.

## Disseminated Infection

In approximately 2% of patients with gonorrhea, disseminated gonococcal infection may arise, usually originating from asymptomatic infection. It manifests most often as an asymmetric oligoarthritis with a predilection for knees, ankles, and large and small joints of the upper limb.

Tenosynovitis occurs frequently. On the skin lesions may be seen presenting classically as tender necrotic pustules. Gonococcal arthritis accounts for as much as 20% of acute arthritis in young adults in the tropics.<sup>6</sup> Rarer manifestations of disseminated gonococcal infection include endocarditis and meningitis. Disseminated infections can no longer be expected to respond to penicillin as in the past.

## Ocular Gonococcal Infections

Ocular gonococcal infection in adults, which is presumed to follow autoinoculation with a contaminated finger in most cases, is a common and potentially blinding complication in developing countries. It presents as an acute purulent conjunctivitis, which may progress rapidly to corneal perforation in the absence of adequate systemic antimicrobial treatment.

## Laboratory Diagnosis

The definitive diagnosis of gonorrhea rests on the isolation of *N. gonorrhoeae*. The demonstration of gram-negative, intracellular diplococci in urethral smears has sensitivity and specificity of over 95% for the diagnosis of gonorrhea in men, but both sensitivity and specificity are considerably lower in women. In disseminated infection, specimens from joints, blood or skin lesions give a rather poor yield and the organism may be isolated more readily from the genital tract. When cultures are to be made, the sites for swabbing should be determined by the history and examination findings. In men, it is good to obtain a urethral specimen by insertion and rotation of a swab in the urethra for 5 seconds.

For women, the ectocervix should be wiped clean and a swab should be inserted into the cervical os and rotated for 10 seconds. Rectal swabs are best obtained through a proctoscope. *N. gonorrhoeae* is a delicate organism, highly susceptible to drying, and prompt inoculation of media and careful adherence to recommended laboratory techniques is important to maximize isolation rates. Newer techniques for gonococcal detection are the molecular methods using nucleic acid amplification tests (NAATs). Although the use of molecular methods has increased in the last few years, culture remains important for the determination and monitoring of antimicrobial resistance in *N. gonorrhoeae*.

## Treatment

A large proportion of isolates of *N. gonorrhoeae* is now resistant to penicillins, tetracyclines, and quinolones. The most effective and recommended class of antibiotics is the third-generation cephalosporins with careful monitoring as treatment failures have been reported recently with the oral third-generation cephalosporins. Ideally, treatment should provide us a single dose of oral regimen to improve compliance, but with the recent emergence of highly resistant strains, parenteral therapy is becoming more the preferred route of administration to maintain high cure rates. The dose administered should give a serum level of at least three times the minimum inhibitory concentration for 8 or more hours.

The current World Health Organization (WHO) treatment recommendations for uncomplicated gonorrhea are ceftriaxone 250 mg intramuscularly as a single dose, or cefixime 400 mg orally as a single dose. Where available, spectinomycin 2 g by intramuscular injection, as a single dose, can be used as an alternative. Treatment of sexual partners should extend to all individuals exposed within 2 weeks of the onset of symptoms in the index patient. In the case of asymptomatic infection, all sexual partners within 4 weeks of diagnosis should be offered treatment. Some authorities recommend that all sexual partners within the previous 3 months should be screened and treated. If the syndromic approach to diagnosis and treatment is being pursued, combined treatment for both gonorrhea and chlamydial infection should be given to all patients with urethral discharge.

## CHLAMYDIAL INFECTIONS

The demonstration in 1909 of chlamydial inclusions in cervical scrapings from the mother of an infant with inclusion conjunctivitis and in urethral scrapings from her male partner laid the basis for our understanding of genital chlamydial infections, but it was not until it became possible to isolate *Chlamydia trachomatis* (*C. trachomatis*) in tissue culture in 1965 that the extent of the morbidity due to this organism became clear.

## Causative Pathogens and Pathogenesis

*C. trachomatis* is the most prevalent sexually transmitted bacterial pathogen in industrialized countries, and appears to be at least equally prevalent in developing countries.<sup>7</sup> Studies in industrialized countries and some parts of Africa have shown that genital chlamydial infection is more prevalent in younger age groups, even after taking differences in sexual activity into account, implying that some degree of protective immunity may develop after natural infection. *C. trachomatis* is a gram-negative bacterium, which is an obligate parasite of eucaryotic cells. The genus *Chlamydia* has a unique life cycle. The metabolically inert infectious elementary body has a rigid cell wall and is adapted for extracellular survival. It preferentially attacks columnar epithelial cells. After entering the host cell, it differentiates over a number of hours to the metabolically active reticulate body, which divides by binary fission until an intracellular inclusion is formed. The life cycle is completed when reticulate bodies condense to form elementary bodies, which are released from the inclusion after lysis of the host cell. A number of serotypes of *C. trachomatis* have been identified by the microimmunofluorescence test. Serotypes A to C cause ocular infection in trachoma endemic areas, whereas serotypes D to K cause genital tract infections worldwide. Serotypes L1, L2, and L3 are more invasive both *in vitro* and *in vivo*, and cause lymphogranuloma venereum (LGV). The pathological hallmarks of infection with *C. trachomatis* are: (i) the sub-epithelial lymphoid follicle, and (ii) fibrosis and scarring. The latter may progress for months and years even in the absence of chlamydial organisms demonstrable by conventional means. The host immune system is believed to play an important part in the pathogenesis of chlamydial infections.

## Clinical Presentation

The clinical spectrum of disease due to chlamydial infection is similar to that seen in gonococcal infection. Men present with urethritis, giving rise to urethral discharge that can be indistinguishable from that seen with gonococcal infection. However, characteristically chlamydial infections present with scanty discharge. In a proportion of cases, epididymo-orchitis may ensue. It is possible that urethral stricture is a late sequela of chlamydial urethritis.

## Diagnosis

The advent and introduction of NAATs have made it possible to expand testing for chlamydial infections, using non-invasive

**Table 54.1:** Treatment Combination Options for Urethral Discharge Syndrome

Condition	First line	Second line
Treatment options for gonorrhea	Ceftriaxone 250 mg intramuscularly, single dose Or Cefixime 400 mg orally, single dose	Spectinomycin 2 g IM as a single dose (in pregnant or penicillin-allergic patients) Or Gentamicin <sup>†</sup> 240 mg IM single dose
Treatment options for Chlamydia	Azithromycin 1 g single oral dose Or Doxycycline 100 mg twice daily for 7 days	

<sup>†</sup>Note that clinical efficacy has been documented for urethral gonococcal treatment, but there is limited data correlating laboratory minimal inhibitory concentrations (MICs) with clinical observations.

methods and samples, such as first catch urine and vaginal swabs. Where affordable, the use of NAATs is preferable for the diagnosis of chlamydial infections. Although NAATs are more sensitive than antigen detection tests or isolation, they remain expensive and require good laboratory facilities.<sup>8</sup> Serology has no place in the diagnosis of uncomplicated chlamydial infections with the exception of the more invasive LGV. Serology, however, is the method of choice for the diagnosis of neonatal chlamydial pneumonia. Reasons for this are that it is only possible to distinguish between antibodies to the various species of *Chlamydia* by the micro-immunofluorescence test, which is subjective and labor intensive. Other serological tests may give false positive results due to infection with the highly prevalent respiratory tract pathogen, e.g., *Chlamydia pneumoniae*.

## Treatment

*C. trachomatis* remains sensitive to tetracyclines and erythromycin, and single dose treatment with azithromycin is effective in uncomplicated chlamydial infection.<sup>9</sup> Table 54.1 gives a summary of current treatment recommendations for urethral discharge syndrome which combines the treatment of gonococcal infections and chlamydial infections.

## TRICHOMONIASIS

Trichomoniasis is caused by the flagellated protozoal parasite *Trichomonas vaginalis* (*T. vaginalis*). When viewed under the microscope on a wet mount, a viable organism can be recognized easily by the lashing movements of its flagella. *T. vaginalis* is the single most common curable STI worldwide, with an estimated 248 million cases occurring annually.<sup>10</sup> *T. vaginalis* has been isolated in 1–15% of cases of non-gonococcal urethritis in men. Recent community-based studies in East Africa have found prevalences of around 10% among truck drivers in Mombasa<sup>11</sup> and rural men in Tanzania.<sup>12</sup> Sexual contact is the usual mode of infection, but the parasite is known to survive on inanimate objects providing moist conditions; thus, fomites may occasionally

play a role in transmission. In women, the parasite attaches to the vaginal mucosa and competes nutritionally with the protective vaginal lactobacilli. This results in disappearance or diminution in number of lactic acid producing lactobacilli and leads to a corresponding rise in pH (4.5 and above) of the vaginal milieu. There is an inflammatory response with polymorphonuclear leukocytosis.

## Clinical Features

In men the infection is commonly asymptomatic. When symptomatic, probably in about 50% of cases, the most common presentation is with urethral discharge and, sometimes, dysuria.

## Diagnosis

Commonly, diagnosis is either by direct microscopy of a wet-mount preparation or culture using Diamond medium. However, *T. vaginalis* is difficult to demonstrate in male patients, and culture of a centrifuged first catch urine specimen may be the most sensitive method of a definitive diagnosis. NAATs offer the most sensitive diagnostic option, but they remain expensive and require good laboratory practice.

## Treatment

Metronidazole has been the mainstay of treatment for infection with *T. vaginalis*.

## MYCOPLASMA AND UREAPLASMA INFECTIONS

*Mollicutes* are a class of organisms that have developed from anaerobic bacteria by gene deletion. The genera *Mycoplasma*, *Ureaplasma*, *Acholeplasma*, *Anaeroplasm*, and *Asteroleplasma* make up more than 120 species, generally referred to as mycoplasmas. Of some 16 mycoplasmas detected in the human species, six appear to have the genitourinary tract as their primary site of colonization. These are *M. hominis*, *M. primatum*, *M. genitalium*, *M. spermatophilum*, *M. penetrans*, and *U. urealyticum*. Although infants may become colonized with genital mycoplasmas during birth, colonization after puberty occurs primarily as a result of sexual contact.<sup>13</sup> *M. genitalium*, as a new pathogen among the mycoplasmas, was first isolated in cultures of urethral discharge from men with non-gonococcal urethritis in the early 1980s and subsequently reported as a possible pathogen in male urogenital infections.<sup>14,15</sup> A number of studies have since implicated the mycoplasmas in the etiology of non-gonococcal urethritis, including studies in which investigators inoculated themselves intraurethrally with ureaplasma strains.<sup>16</sup>

## Clinical Features

The clinical features of *Mycoplasma* infection are similar to those caused by chlamydial infection. The urethral discharge may be significant or scanty and mucoid.

## Diagnosis

The detection of *Mycoplasma* and *Ureaplasma* in the male genitourinary tract can be done by collecting and testing a urethral swab specimen and/or a first-catch urine specimen by culture. However, *M. genitalium* is too fastidious to culture and antigen detection has not had great success in identifying the organism. The best results are obtained by using the polymerase chain reaction (PCR) technique.

## Treatment

Since diagnostic facilities for these organisms are not readily available, especially in resource-limited settings, management should depend being aware of clinical conditions in which *Mycoplasma* may be implicated. Accumulated evidence suggests that *C. trachomatis*, *M. genitalium*, and occasionally *Ureaplasma* are causes of non-gonococcal urethritis. The usual treatment of non-gonococcal urethritis with either tetracyclines or erythromycin is effective.

## Management of Urethral Discharge Syndrome

Early diagnosis and effective treatment of STIs are essential components of STI control programs. The traditional method for STI diagnosis has been through laboratory diagnosis of the etiological agent as outlined above. This is still the method of choice in many parts of the industrialized world. However, as can be inferred from the diagnostic procedures and requirements above, this approach is too expensive for most resource-constrained countries in terms of diagnostics, infrastructure, manpower, and maintenance. Additionally, it often results in delays in diagnosis and treatment and, in the case of urethral discharge, may miss the presence of mixed infections.

To address the limitations of laboratory-based etiological diagnosis, the WHO developed and advocated the use of treatment algorithms for a syndromic approach. The syndromic management of STI has advantages which include provision of care without delay, cost savings by not using expensive laboratory tests, treatment at first visit at the first port of call for the patient, and patient satisfaction. Management is simplified by the use of clinical flowcharts and allows time in the consultation to provide simple education messages, discuss partner notification and promote condoms. Antimicrobial therapy is provided at once to cover the majority of pathogens presumed responsible for that syndrome, in that specific geographical area. In the syndromic management, all male patients complaining of urethral discharge should be examined for evidence of discharge. If none is seen, the urethra should be gently massaged from the ventral part of the penis towards the urethral meatus. As indicated in the causative pathogens above, the major bacterial causes of urethral discharge are *N. gonorrhoeae* and *C. trachomatis*. The syndromic management treatment of a patient with urethral discharge should adequately cover these two organisms. Thus, syndromic therapy should include effective treatment for uncomplicated gonorrhea

plus effective therapy for *Chlamydia*. It is recommended that patients be advised to return, where possible, if symptoms persist 7 days after start of therapy. An example of an algorithm for urethral discharge is shown in Fig. 54.2. Table 54.1 gives current effective therapeutic options for these organisms. For purposes of compliance and acceptability single dose oral therapy, whenever possible, should be given. This combination treatment has been shown to be both highly efficacious and cost-effective. In a study in Bandung, Indonesia, the clinical effectiveness of the approach was seen in 97% of patients. The positive predictive value was high (adjusted to 97%) and the algorithm was feasible and acceptable at the primary healthcare setting.<sup>17</sup> In a multi-centre study in Brazil syndromic management of urethritis in men had a higher sensitivity for both gonorrhea and *Chlamydia* (98.8% and 91.4%, respectively) than that of a clinician's presumptive diagnosis (86.3% and 48.6%, respectively).<sup>2</sup> In this study, adding laboratory investigations improved the specificity and positive predictive value only for gonorrhea, but not for *Chlamydia*. Researchers from other parts of the world have similar conclusions for the urethral discharge syndromic management.

There is accumulating evidence suggesting high prevalence of *T. vaginalis* in men with urethral discharge. In those settings, treatment for the protozoan should be part of the syndromic

management in men, either at the first instance or when urethritis persists or recurs without re-infection.

### PERSISTENT OR RECURRENT URETHRITIS

Persistent or recurrent urethritis may be due to drug resistance, poor compliance or re-infection. In few patients, *Trichomonas vaginalis* may be the responsible pathogen, which may not have been covered in the initial treatment algorithm.

If re-infection has been reliably excluded, assessment should be made to ascertain that the first line treatment given was an effective recommended regimen. All cases of treatment failure to the first line treatment should be accurately recorded and reported to the relevant health authority. These reports will form part of the early warning system and should alert the authorities to the possibility of antimicrobial resistance in the community. A more systematic investigation should be initiated in collaboration with a national reference laboratory when cases of treatment failure occur with increased frequency or in large numbers (for example, five separate cases in a month). The public health system response then involves identifying the proportion of isolates which show resistance. When the proportion of resistant strains obtained from persons with gonococcal infection is at a level of 5% or

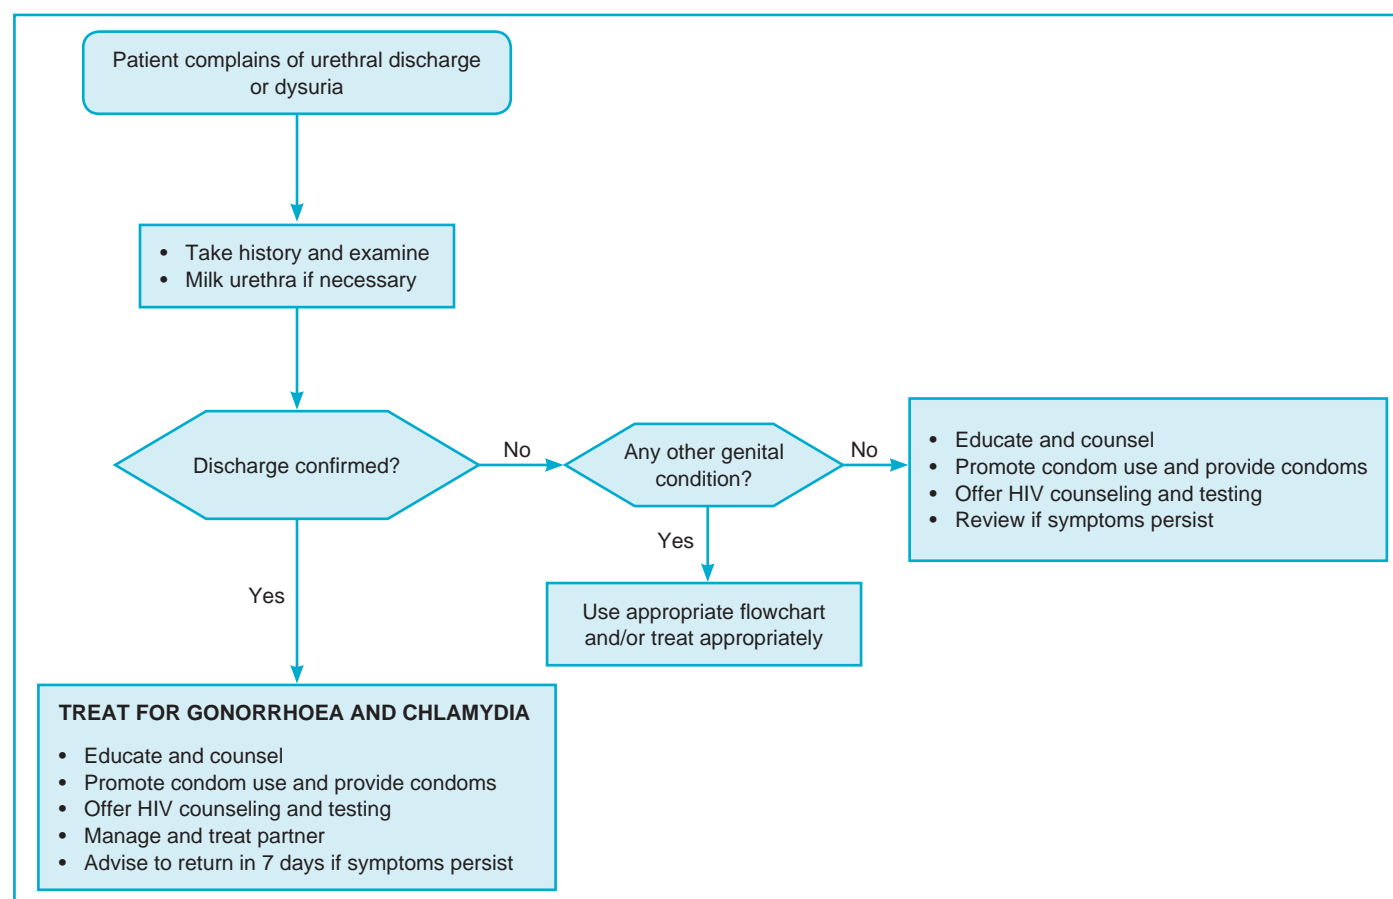

Fig. 54.2: Flowchart for the syndromic management of urethral discharge.

more, or when any resistance is detected in key populations with high rates of gonococcal infection (for instance in men who have sex with men or sex worker populations), steps need to be taken to review and modify the national treatment and management guidelines while enhancing surveillance.

Multiple drug-resistant *C. trachomatis* infection has been reported in the past. This may cause persistence of urethritis after adequate treatment in an occasional patient.<sup>18</sup> Other possible causes include infection with *Ureaplasma urealyticum* and *Mycoplasma genitalium*.<sup>19</sup>

## NOTIFICATION AND MANAGEMENT OF SEXUAL PARTNERS

The sexual partners of STI patients are likely to be infected themselves and should be offered treatment. Further transmission of STI and re-infection are prevented by referral of sexual partners for diagnosis and treatment. Female partners of male STI patients may well be asymptomatic; thus, partner notification and management offer an opportunity to identify and treat people who otherwise would not receive treatment. Partner notification should be considered whenever an STI is diagnosed, irrespective of where care is provided. Notification can be by patient referral or by provider referral. In patient referral an infected patient is encouraged to notify partner(s) of their possible infection without the direct involvement of healthcare providers, while in provider referral healthcare providers or other health-care workers notify a patient's partner(s).

Partner notification should be conducted in such a way that all information remains confidential. The process should be voluntary and non-coercive. The aim is to ensure that the sexual partner(s) of STI patients, including those without symptoms, is/are referred for evaluation. Management of sexual partners is based on knowledge of the index patient's diagnosis (syndromic or specific).

The following strategies can be adopted for the treatment of partners:

- Offer immediate epidemiological treatment (treatment based solely on the diagnosis of the index patient) without any laboratory investigation.
- Offer immediate epidemiological treatment, but obtain specimens for subsequent laboratory confirmation.

The strategy selected will depend on:

- risk of infection,
- severity of disease,
- availability of effective diagnostic tests,
- likelihood of a person returning for follow-up,
- availability of effective treatment,
- likelihood of spread if epidemiological treatment is not given,
- available infrastructure for follow-up of patients.

The WHO recommends that epidemiological treatment (with the same treatment regimen used for the index patient) should be given to all sexual partners without delay.

# Epididymitis and Epididymo-orchitis

Francis Ndowa • Sibongile Dlodlu

# 55

## Introduction

The epididymis is elongated, tightly coiled duct of up to 4.5 meters in length situated at the posterior border of the testis. It provides for transit, maturation, and storage of spermatozoa which are formed in the testis. During passage through this length of the organ, differentiated sperm cells undergo maturation processes including motility and the potential to fertilize an egg.

## Epidemiology and Etiology

Epididymitis, an inflammation of the epididymis, is common and responsible for a significant loss of time from work for men. It is often associated with infection of the testis; in that case the term “epididymo-orchitis” is used. However, some organisms tend to cause infection only of the epididymis. It has been reported that the incidence of epididymitis may range from one to four per 1000 men per year. The average duration that men with epididymitis are absent from work is 1 week.<sup>1</sup> With increased understanding of the condition, a decrease in morbidity can be achieved. The peak incidence for epididymitis is between 20 and 29 years of age, but close monitoring is needed to capture any changes in epidemiology due to changes in sexual behavior with more and more boys becoming sexually active at a younger age.

Acute epididymitis is uncommon in infants and is usually associated with underlying genitourinary tract abnormalities. In prepubertal boys, the usual etiologic agents of epididymo-orchitis are coliforms, *Pseudomonas*, or mumps virus infections. In sexually active adolescents and men below the age of 35 years, epididymo-orchitis is mostly due to sexually transmitted pathogens such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.<sup>2,3</sup> Without the use of antibiotics, up to 30% of gonococcal urethritis may end up in acute epididymitis in this sexually active population. In older men (over 35 years of age), on the other hand, coliforms are more commonly implicated as a complication of urinary tract infection. In this older age group, the organisms commonly identified are *Escherichia coli*, *Klebsiella* spp., *Pseudomonas aeruginosa*, *Proteus*, or *Staphylococcus epidermidis*. Increasingly, coliforms are responsible for the higher risk and increased frequency of acute

epididymitis in men who have unprotected anal sex with men.<sup>4</sup> In heterosexual men, coliforms more often cause epididymo-orchitis, if there has been recent catheterization or instrumentation.

Other causative organisms of epididymitis, secondary to systemic infections, include *Mycobacterium tuberculosis*, *Brucella* spp., *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Treponema pallidum*. In post-mortem analyses, it would seem that cases of tuberculous epididymitis occur only if patients have prostatic, renal, or seminal vesicular involvement.<sup>5</sup> Furthermore, tuberculous epididymitis tends to present with bilateral inflammation in most cases compared to the mostly unilateral manifestation of coliforms and sexually transmitted pathogens. A high index of suspicion needs to be kept for tuberculous epididymitis in settings of high HIV prevalence as tuberculosis becomes more common in men in such settings. In such patients as well as in post-transplant patients on immunosuppressive therapy, it is important to keep in mind other opportunistic infections known to cause epididymitis, such as histoplasmosis, coccidioidomycosis, and cryptococcosis. Infection with *Candida albicans*, *Candida glabrata*, cytomegalovirus, and *Haemophilus influenzae* can also occur in these patients.

## Clinical Presentation

Acute epididymitis may be sudden or gradual. Clinically, the patient complains of a painful swollen testis (Fig. 55.1), which is unilateral in about 10–30% of patients with a gonococcal infection.<sup>6</sup> Men with epididymitis due to sexually transmitted pathogens, such as *C. trachomatis* or *N. gonorrhoeae*, often have a history of urethral discharge or dysuria, although some may not show any urethral signs of the infection. History of a recent sexual exposure may be obtained and would be a useful pointer to diagnosis. Epididymitis occurs in either of the testicles with equal frequency. Fever is present in approximately 75% of the patients and chills are reported mostly in elderly patients.<sup>7</sup> Pain may also be felt beyond the scrotum in the inguinal region or the abdominal flank on the affected side. Generally, younger patients below 35 years of age show less severe symptoms. The

**Fig. 55.1:** Scrotal swelling with erythema on the surface due to chlamydial epididymitis. Patient had urethritis 8 days ago, received treatment only for gonorrhea, resulting into development of epididymitis due to untreated Chlamydia.

inflammatory process begins in the epididymal tail and extends to the rest of the tube and the testicle, although inflammation of the testis itself is rare. Examination reveals an enlarged and tender epididymis on the affected side with erythema of the overlying scrotal skin in the region of the epididymis (Fig. 55.1).

Simple examination during an acute infection may not easily distinguish between the testis and the epididymis as both structures may be inflamed. The spermatic cord may be swollen and tender. Careful examination of the urethra may reveal a discharge or microscopic urethritis on a Gram stain of a urethral smear. Occasionally, there may be an accompanying inflammatory hydrocele.

## Differential Diagnosis

Testicular torsion, caused by twisting of the spermatic cord, is the most important differential diagnosis of acute epididymitis as it rapidly leads to infarction of the testis. Testicular torsion has a short history of onset and the testis usually lies higher and transverse within the scrotum. This diagnosis is more frequent in prepubertal children. Testicular torsion is a surgical emergency and surgical exploration may need to be considered in this age group.

Tuberculous epididymitis is an unusual but important form of epididymitis, and this is of relatively greater importance in

areas of high prevalence of tuberculosis.<sup>8</sup> Clinically, it is usually bilateral, non-tender, and firm to palpation. In brucellosis, usually due to *Brucella melitensis* or *Brucella abortus*, an orchitis is likely to be clinically more evident than an epididymitis.

Mumps can also cause an acute orchitis and a history of recent mumps infection should be excluded. In this infection, testicular swelling usually develops within a week of parotid swelling.

The differential diagnosis should also include other non-infectious causes of testicular swelling. These include trauma and testicular malignancy. It is important to realize that the peak ages for epididymitis are similar to those for testicular tumors. Thus, whereas a painless testicular mass almost always indicates a tumor, the presence of pain does not necessarily rule out a tumor.

There have also been reports of epididymitis in patients with Behçet disease, polyarteritis nodosa, and Henoch–Schönlein purpura. Other conditions that may complicate a clear diagnosis of epididymitis are varicoceles, herniae, and spermatoceles.

## Complications

The following are some of the encountered complications of acute epididymo-orchitis, and are usually a consequence of delayed treatment:

- Scrotal abscess
- Testicular infarction
- Infertility or decreased fertility
- Testicular atrophy
- Chronic epididymitis and orchalgia

When the inflammation is due to coliforms, severe inflammation may lead to formation of an abscess, testicular infarction, and testicular atrophy.<sup>8</sup> If not effectively treated, epididymitis can lead to decreased fertility. If patients present with bilateral epididymitis and bilateral occlusion of the vas deferens or epididymis, they may become totally infertile. Retrospective epidemiologic results also support an association between positive Chlamydia serology and male infertility. However, in most of such studies, the association does not reach the level of statistical significance due to small sample size.<sup>9</sup> Chronic epididymitis presents with unilateral or bilateral scrotal pain, sometimes associated with chronic testicular pain (chronic orchalgia), either intermittent or persistent for three or more months in duration. The etiology can be associated with inflammatory, infectious, or obstructive factors but, in many cases, no identifiable etiology can be identified.<sup>10</sup>

## Laboratory Diagnosis

Where laboratory investigation is possible, examination of the urine and urethral smear is a very helpful procedure in differentiating epididymitis from testicular torsion. Urine microscopy should be performed to detect pus cells. Torsion does not give rise to pyuria. A midstream urine sample, without centrifugation, can be useful to make a presumptive diagnosis of epididymitis, if bacteriuria is confirmed as in the case of coliforms and *Pseudomonas* infections. A midstream urine culture should

be performed in all cases of suspected epididymitis. A Gram stain of a urethral smear may aid in the diagnosis of *N. gonorrhoeae*. Detection of *C. trachomatis* should also be attempted, where possible, as this pathogen can be the sole cause of epididymitis without *N. gonorrhoeae* or other pathogens.<sup>2</sup> Culture of an epididymal aspirate has been tried to establish a diagnosis of epididymitis in special circumstances. This is not recommended in an out-patient consultation. Some of the special cases that warrant this procedure are recurrent epididymitis in which the etiologic agent cannot be established, failure to respond to effective antimicrobial treatment and epididymitis found on surgical exploration for suspected testicular torsion.

In many settings, however, a laboratory diagnosis cannot be performed for reasons of cost, lack of diagnostic equipment or lack of trained laboratory technicians. In such cases, a syndromic approach to the management of testicular pain and swelling should be followed.

## Syndromic Management of Acute Scrotal Swelling

If history suggests it and a urethral discharge is detected then the epididymo-orchitis is most likely secondary to either or both of the sexually transmitted pathogens, *N. gonorrhoeae* and *C. trachomatis*. It should be remembered that the absence of a urethral discharge does not exclude the presence of STI—history is, therefore, of paramount importance in making the decision. For example, in a report of young military recruits with epididymitis, 16% had gonococcal infection, but only 50% of them with the infection had urethral discharge.<sup>11</sup> Figure 55.2 shows a flow chart that can be used to assist in the syndromic management of a scrotal swelling or scrotal pain. If no laboratory diagnosis is possible, it is recommended that the patient be treated at the same time for the two pathogens (Fig. 55.2). Generally, the management of the

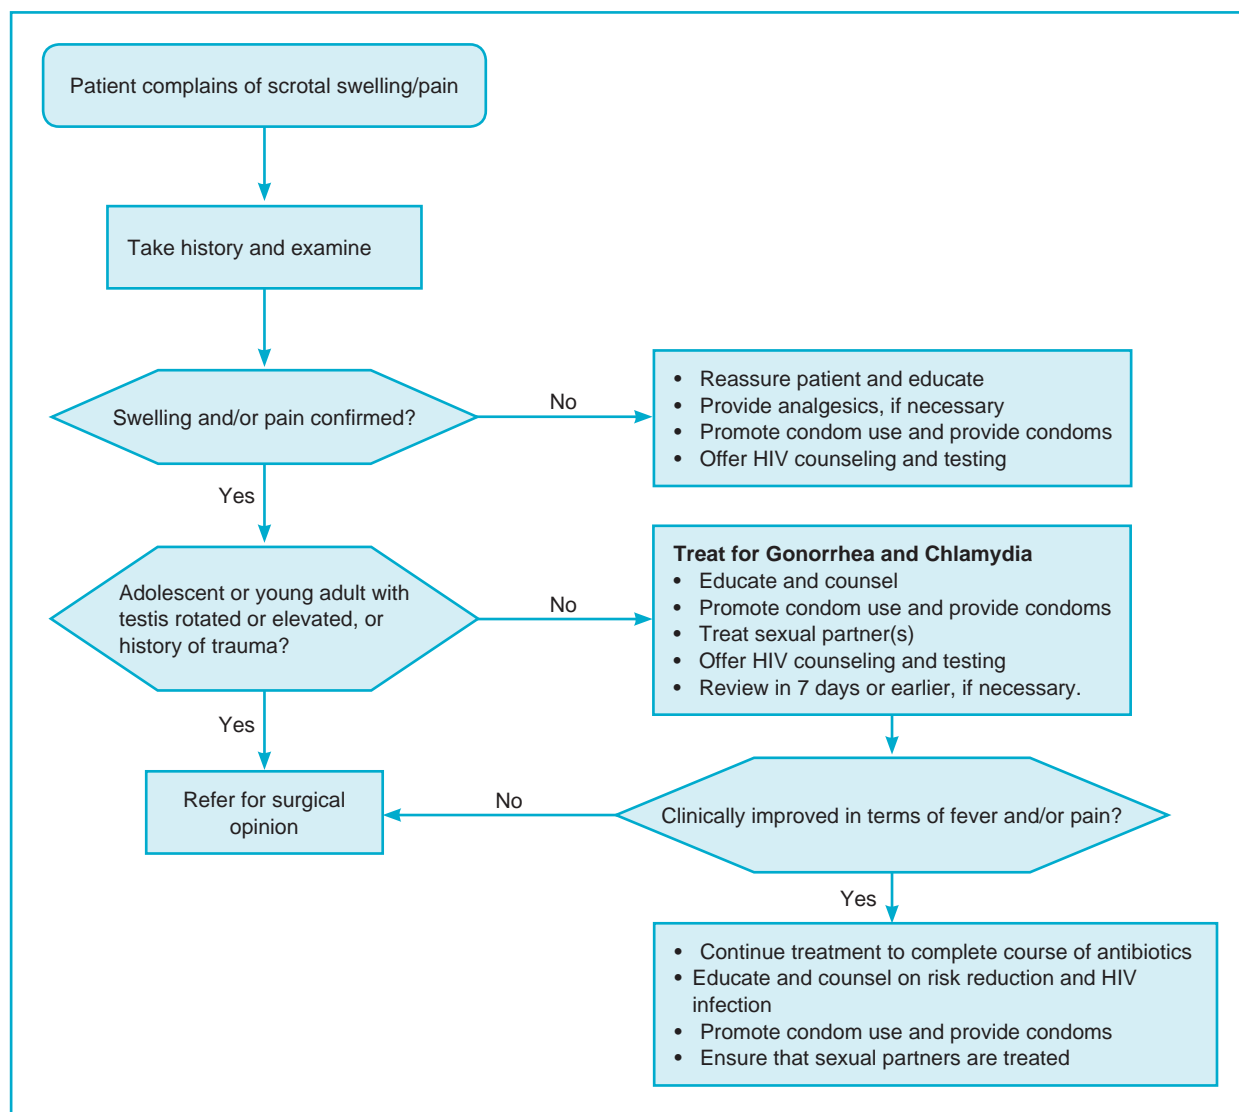

Fig. 55.2: Scrotal swelling management flowchart.

patient includes bed rest, scrotal support and elevation, pain relief, and appropriate antibiotics. Elevation can be achieved by placing a towel, or some other such material, between the patient's legs while in the supine position. While lying down, scrotal support alone is not sufficient as the scrotum would be dependent and drainage will be delayed. Bed rest should be continued until tenderness has resolved. Pain relief can be provided by the use of non-steroidal anti-inflammatory drugs. Various other combinations have been tried and shown to hasten the disappearance of pain ahead of inflammatory resolution. Injection of the spermatic cord with xylocaine hydrochloride has been shown to relieve pain immediately and more effectively than the use of antibiotics alone.<sup>12</sup>

Syndromic treatment should be as follows:

- Effective therapy for uncomplicated gonorrhea plus effective therapy for Chlamydia. A possible syndromic regimen, after taking into account locally determined antimicrobial susceptibility patterns, may include:
  - ceftriaxone, 250 mg, IM, single dose for gonococcal infections PLUS
  - doxycycline, 100 mg, orally, twice daily for 10 days or azithromycin 1 g orally as a single dose, for chlamydial infections.
- Patients in whom gonorrhea and/or Chlamydia are suspected to be the cause of the epididymitis, management of sexual partners must not be overlooked. Sexual partners should be treated for the same infections as the index patient.
- For acute epididymitis most likely caused by enteric organisms, appropriate antibiotics should be given. For example, ofloxacin, 400 mg orally, twice daily for 10 days or levofloxacin 500 mg once daily for 10 days. As *E. coli* and other coliforms are demonstrating increasing resistance to trimethoprim-sulfamethoxazole, this combination antibiotic should not be used without laboratory guidance in terms of susceptibility of the organism.
- For severe infections, consideration should be given to intravenous broad-spectrum antibiotics directed against coliforms and *P. aeruginosa*.

Potentially epididymitis has serious consequences in young people. Therefore, more effort should be made to prevent it from occurring. Urethritis should be treated effectively and promptly at the first port of call for any patient. When epididymitis occurs treatment should be prompt. No justification can be made to withhold the use of antibiotics in suspected infectious epididymitis.

# Abnormal Vaginal Discharge: Syndromic Management

Verapol Chandeying • Nutthaporn Chandeying

# 56

## Definition

The term vaginal discharge has been used synonymously with leukorrhea. It has been defined as whitish discharge, which is not associated with menstruation. When used by the patient, it is considered a symptom, the clinician uses it to describe a sign, and sometimes as diagnosis. As the pathophysiology is becoming more clearly understood, it is apparent that the term “*leukorrhea*” is ambiguous. The symptoms and signs of vaginal discharge are found in diverse physiological to pathological conditions, both local and systemic disturbances. Abnormal vaginal discharge (AVD) is defined as any one of the three presentations: (i) excessive vaginal discharge not associated with menstruation, pre-, mid-, and post-period; (ii) offensive or malodorous discharge; and (iii) yellowish or mucopus discharge.<sup>1</sup>

Vaginal discharge is the most common presenting complaint in women attending gynecologists, general practitioners, and various health clinics for women.

Discordance between degree of AVD as described by the patient and examination findings may occasionally be encountered. Some patients can tolerate persistent discharge without complaint, and eventually deny its presence, although speculum examination shows heavy discharge. On the other hand, many patients complain of offensive/profuse discharge, however, speculum examination reveals no odor/discharge. Patients that need to be investigated include those presenting with symptoms of AVD, with or without concurrent urogenital symptoms.

## Prevalence

It has been estimated that up to one-third of female patients may complain of AVD, however, there are no epidemiological data to support this. AVD can occur in females of all ages, from the neonatal to the postmenopausal period, and it is quite common during pregnancy. Many clinics have reported that more than 70% of pregnant women manifest AVD, due to lower genital tract infection (LGTI).<sup>1</sup> In a study of 240 females of reproductive age with AVD, the prevalence of various causative conditions had been found to be 37.9% for bacterial vaginosis (BV), 33.7%

for mucopurulent cervicitis (MPC), 29.1% for non-infective leukorrhea (NIL), 22.0% for vaginal candidiasis (VC), and 4.1% for vaginal trichomoniasis (VT). Among these 240 women, 15.8% had infection with two organisms, and 0.4% with more than two organisms. Detection of *Chlamydia trachomatis* from endocervical secretion of women who had MPC is obtained up to 12.3%. One-sixth of infective causes are mixed infection.<sup>2</sup>

## Normal Discharge

The normal discharge is floccular in consistency (similar to coarse granules of cassava starch gluten), whitish, and non-malodorous. The volume may vary considerably between individuals, from minimal staining of undergarment to profuse discharge. The normal pH is acidic, ranging from 3.5 to 4.5 due to activity of Döderlein lactobacilli, which convert glycogen into lactic acid. Acid pH may exist even when lactobacilli are decreased in number or absent. This is thought to be due to secondary fermentation of endocervical mucus by vaginal flora.<sup>3</sup> Therefore, a decreased number of lactobacilli do not always imply infectious conditions.

The vaginal pH rises to 7.0 within just seconds after ejaculation.<sup>4</sup> Cervical pH is alkaline, with a peak pH during the periovulatory period.<sup>5,6</sup> The cellular contents of the discharge are composed of sloughed cells of cervical columnar and vaginal squamous epithelium. The bulk of discharge consists of serous vaginal transudate and lubricating cervical mucus.<sup>1,7-9</sup>

## VULVOVAGINAL SOURCE

The vaginal canal, being of ectodermal origin, consists of stratified squamous epithelium. There are no sweat, sebaceous, and other types of secretory glands in vaginal epithelium. The *portio vaginalis* of the cervix, derived from Müllerian duct system, projects into the upper end of vagina. At the caudal end is the vulva, lined by squamous epithelium; containing secretory, sweat and sebaceous glands, and hair follicles. The paraurethral (Skene glands) and greater vestibular (Bartholin) glands are located at each side of the vestibule. Skene glands are vestigial tubules, 1–2 cm in length, lined with columnar epithelial. Bartholin glands

are tubuloalveolar mucous glands, with acini lined by columnar epithelium. The mucus secretions of these glands bathe the surface of the vestibule and the introitus, but probably contribute little increment to the vaginal secretions.<sup>1</sup>

Vaginal fluid is largely derived from serum transudate in vaginal beds that seeps from capillaries through intercellular channels. Smaller amount of fluid is derived from Bartholin glands, endometrium, and fallopian tubes. White blood cells are present only in small numbers in women without LGTI.<sup>10</sup> Beside cellular debris, the vaginal transudate is principally composed of water and electrolytes, facultative microorganisms, and organic compounds such as fatty acids, proteins, and carbohydrates.<sup>11</sup>

BV is characterized by an absence of lactobacilli and, thus, an elevated pH. A low vaginal pH may inhibit CD4 lymphocyte activation and therefore decrease HIV target cells in the vagina;<sup>12</sup> conversely, an elevated pH may make the vagina more conducive to HIV survival and adherence.<sup>13</sup>

Hormonal change, “sex steroid hormone starvation” results in a decreased genital blood supply, loss of vulvar adipose tissue, an increase in pH to above 5.0 of the vaginal secretions, thus predisposing the vagina to infection.<sup>8,14</sup> In addition, desquamation of the mature epithelium and traumatization of the mucosa may result in a break of its continuity, allowing bacterial penetration and possible infection.

## CERVICAL SOURCE AND BEYOND

The cervix is a principal source of vaginal secretion. The stratified squamous epithelial lining of the *portio vaginalis* is continuous with vaginal fornices. At the external os, this epithelial surface changes abruptly to a high columnar epithelium, which lines the cervical canal up to the internal os, and lines the cervical glands as well. The cervical glands are of simple and tubuloalveolar type that secrete thick and viscid mucus.

The uterus contributes little to the secretion of vaginal canal, despite the presence of endometrial surface and numerous glands, lined with highly secretory columnar epithelium. The secretion of these cells undergoes cyclic activity in the elaboration of glycogen, and other nutritive materials in preparation for pregnancy each month. Under normal circumstances, the fallopian tubes contribute nothing to the vaginal secretion. Only in rare instance of a hydrosalpinx, resulting from a salpingitis, it is conceivable that tubal secretions may be expelled into the vagina, in the form of a watery discharge.<sup>1</sup>

## Vaginal Microorganisms

In a healthy woman, the vaginal flora consists of a variety of organisms. Besides *Lactobacillus* and *H2O2*-positive *Lactobacillus*, it may also include anaerobic gram-negative rod, *Bacteroides ureolyticus*, beta-hemolytic and non-hemolytic streptococci, *Candida albicans*, diphtheroids, enterococci, *Escherichia coli*, *Fusobacterium nucleatum*, *Mobiluncus* spp., *Mycoplasma hominis*, *Micrococcus pyogenes*, *Peptostreptococcus* spp., *Prevotella bivia disiens*, *Staphylococcus epidermidis*, and *Ureaplasma urealyticum*.

*Lactobacillus* species have been recovered from 96% of the normal women, whereas, coliforms are more common in the vagina before puberty than after puberty. The lower genital tract resembles the nasopharynx in many aspects, such as epithelial surface and mucous secreting glands. Both are affected in the same way by inflammation and physiological changes. There have similar microbiological flora except *E. coli* and other intestinal organisms, which are present only in the genital tract.<sup>1,15–18</sup>

The vaginal ecosystem is a complex environmental condition, consisting of interrelationships among the endogenous microflora, metabolic products of the microflora, host estrogen, and the pH. Vaginal inflammation and infection occur when the vaginal ecosystem is altered. When the balances of microorganisms' changes, potentially pathogenic endogenous microorganisms that are part of the normal flora (e.g., *C. albicans* in cases of VC, and *Gardnerella vaginalis* synergistic with anaerobic bacteria in cases of BV) proliferate and lead to overt infection. Little is known about factors that contribute to the overgrowth of normal flora. Exogenous sexually transmitted microorganisms such as *Trichomonas vaginalis*, *Neisseria gonorrhoeae*, and *Chlamydia trachomatis* are the pathogenic agents.

## Etiological Factors

Apart from being physiological and non-infective conditions, four major causes of cervicitis and vaginitis include MPC, BV, VC, and VT. Infections of the cervix represent a reservoir of pathological microorganism, and may lead to two possible types of complications: (i) ascending intraluminal spread from the cervix often produces endometritis (silent pelvic inflammatory disease [PID]) and eventually acute salpingitis (overt PID); and (ii) ascending infection during pregnancy results in chorioamnionitis, premature rupture of membrane, premature delivery, amniotic fluid infection, and puerperal infection.<sup>19</sup> The systematic approach of AVD will make the diagnosis easy and reduce the rate of complications. Table 56.1 shows the possible etiologic causes of AVD.<sup>20</sup>

## Age-Dependent Physiological Condition

During the first month of life still under the influence of maternal estrogen, the neonatal vagina is lined by stratified squamous epithelium. From the 1 month of age until puberty, the vagina is lined by cuboidal cells, and the pH of the vagina fluid is about 7.0, neutral, or alkaline pH. After puberty, the vagina is lined by stratified squamous epithelium, which becomes much thinner after menopause.<sup>19</sup>

## NEONATE AND INFANT

Neonatal physiological discharge results from the mature stratified squamous epithelium cells under the influence of maternal estrogen. Maternal estrogen is metabolized by 3–4 weeks of age. In early neonate period, the vaginal epithelium is susceptible to with *T. vaginalis* and *C. albicans* due to perinatal transmission, but resistant to *N. gonorrhoeae* and *C. trachomatis*. In the late neonate period, after 1 month of age, vaginal epithelium returns

Chlamydia negative form
Vaginitis
Bacterial vaginosis (BV)
Vaginal candidiasis (VC)
Vaginal trichomoniasis (VT)

Modified from Blackwell.<sup>20</sup>

to a prepubescent stage, and silent shedding of *C. trachomatis*, due to perinatal infection, sometimes occurs.

In older infants, the vaginal cuboidal epithelium is susceptible to *N. gonorrhoeae* and *C. trachomatis* but resistant to *Candida*. Nevertheless, the vaginal infection is rare among infants. *N. gonorrhoeae* is an exception, and thought to represent postnatal acquisition, and is often symptomatic. *C. trachomatis* does not generally reveal the overt signs of infection.<sup>19,21,22</sup>

Typically, neonatal and infantile LGTI are asymptomatic, and the only complaint that the mother notices, is a yellowish stain on the child's diapers or panties.

## PREPUBERTY

Pubertal physiological discharge is a frequently indicative hallmark of impending onset of menarche.<sup>23</sup> Prior to menarche,

the unopposed secretion of estrogen from the ovaries stimulates vaginal and cervical secretion. The discharge during this period is thin and mucoid, which infrequently soils the undergarment. This discharge may be interpreted by an adolescent or her mother, as an evidence of infection.<sup>24</sup> It ultimately subsides with the onset of cyclic progesterone activity.

## CHILDBEARING AGE

The amount of discharge is usually sufficient to keep the vaginal wall moist, but usually not stain the undergarment. The discharge may be sufficient to soil few areas of the undergarment in pre- and post-menstrual period. The discharge often transiently increases in the mid-cycle due to stimulation of the endocervical glands by estrogen. Concurrently, Mittelschmerz or mid-cycle unilateral pelvic discomfort associated with ovulation is not uncommon, usually mild, and rarely lasts more than 24 hours.<sup>25</sup> These cyclic variations do not occur when combined (estrogen and progesterone) or progesterone-only contraceptive pills are used, and the ovulation does not occur.

Occasionally, excess fluid may result from exogenous sources, such as semen of recent ejaculation, vaginal douches, and intrauterine contraceptive device (IUCD).

## POSTMENOPAUSAL PERIOD

Following menopause, marked atrophic changes occur in the vaginal epithelium according to diminished estrogen secretion. Occasionally, because of these atrophic changes, there is a thin, serous discharge, which is stained with blood and associated with itching and burning. Small areas of granulation and ulceration along with slight vaginal bleeding may develop.<sup>1</sup> In postmenopausal women, the most common cause of AVD is atrophic vulvovaginitis.

## Excessive Secretion

### PREGNANCY

Physiological discharge, floccular in characteristics, of pregnant women may exceed than 1 ml of amount on speculum examination, due to increased vascularity, congestion of pelvic organs, and cervical hyperplasia. Moreover, the cervix is likely to bleed during pregnancy, owing to direct trauma from penile thrusting.<sup>26</sup>

### SEXUAL AROUSAL

In nonpregnant women, sexual arousal results in an increased discharge, due to secretion from Bartholin glands. The amount of discharge is increasing during pregnancy, and augmented during sexual arousal.<sup>7</sup>

### NON-INFECTIVE CONDITIONS

#### Chemical Irritants

Using of antiseptics, bath additives, deodorants, detergent spermicides, douches, and perfumed soaps can cause chemical

induced vulvovaginitis. Allergic reactions rarely cause the discharge, but often present local reaction. The patient should be advised to avoid the use of such substances. Saline bath may help to reduce vulvar irritation in the acute phase.

Long-term use of tampons has to be avoided, preventing vaginal ulceration. Although the practice of vaginal cleansing should generally be discouraged, some women insist on douching, in which case, mild vinegar solution or water can be used. Multiple douches may increase the amount of discharge, due to drying effect. Douching with commercial preparation leads to cause abnormal shifts in vaginal flora.<sup>27</sup> Intravaginal application is discouraged because of its link with PID.<sup>28</sup>

## Foreign Bodies

Foreign body in the vagina is relatively an uncommon cause of increased vaginal discharge. Cotton wool from tampons often becomes entwined with the thread of IUCD and then acts as a focus for secondary bacterial infection. Similarly, retained tampons and broken sheath may result in persistent bacterial infection, producing a copious, foul smelling discharge. It is necessary to remove the foreign body, and then the vaginal flora will rapidly return to normal.<sup>20</sup>

## GYNECOLOGICAL CONDITIONS

Endocervical polyp may produce a mucoid secretion and blood-tinged discharge. Profuse watery discharge without mucoid element is suggestive of urine, and its presence in the vagina is likely to be urogenital fistula. Urogenital fistula can be caused by radiation.

Following hysterectomy, vaginal vault granulation tissue may result in the excessive discharge of clear character, and eventually slight bloody secretion. All the tumors, whether benign or malignancy in their early stages, can produce the discharge. In benign tumors, the genital secretion can become quite heavy when the size of the tumor increases. Malignant tumors quickly change to produce a blood-stained discharge or flank bleeding quite early in the process. Secondary bacterial infection may add a purulent element to the discharge.

## MEDICATION, NUTRITION, AND SEXUAL PRACTICE

Alternative medicinal drugs, over the counter (OCT) medical products, and nutritional compounds may be associated with either infective or non-infective discharge.<sup>29</sup> These products include antibiotics, antifungals, antiseptics, and hormonal preparations. General health and sexual practices can affect the balance of microorganisms. Vaginal douches, sexual activities, and change in partners sometimes alter the delicate equilibrium of vaginal flora.<sup>30,31</sup>

Use of doxycycline, azithromycin, clotrimazole, and fluconazole has little effect on vaginal colonization by *Lactobacillus*. Uses of oral and vaginal metronidazole lead to an increase in *Lactobacillus*, which has persisted 1 month after therapy. Intravaginal clindamycin use has caused a decrease 1-week

post-therapy, but at 1 month, level of lactobacilli is similar to those in the metronidazole treatment group. Women treated with oral ampicillin have a modest increase in *Lactobacillus* level. Antimicrobial agents, treating vaginitis and cervicitis, do not cause a decrement in colonization of *Lactobacillus*, detecting 1 week to 1 month after therapy.<sup>32</sup>

## INFECTIVE CONDITIONS

Herpes genitalis in its acute stage, when vesicles and superficial ulcers are present, may give rise to vaginal discharge. BV caused by the synergy of *G. vaginalis* and anaerobic bacteria, a set of BV organisms, is a commonest cause of AVD.<sup>2</sup> Other causative pathological organisms include *C. albicans*, *T. vaginalis*, *C. trachomatis*, and *N. gonorrhoeae*. Genital lesions (e.g., warts, syphilitic chancre, chancroid, etc.) may produce discharge. However, there is some doubt whether *M. hominis*, *M. genitalium*, *U. urealyticum* do cause vaginitis and cervicitis.

## Approach to a Patient with AVD

### GENERAL CONSIDERATIONS

AVD develops when the vaginal flora has been altered by the changes in the vaginal environment, or by the introduction of a pathogen that allows the pathogen to proliferate. Despite a limited number of causes, the clinicians often have difficulty in establishing an accurate diagnosis of AVD. The identification of the etiological causes is often over-diagnosed among women, who actually have normal flora. Mixed infection occur frequently, the assessment may be under-diagnosed as one cause.<sup>9</sup> The approach of AVD may be complicated by the wide variety of vaginal preparations available, many of which are self-prescribed and self-administered. With attending their clinicians again and again, persistent symptoms often lead to patients' dissatisfaction, and then switch to seek for a second opinion.

Persistent symptom brings to high cost of repetitive visits, in managed healthcare systems. The frequent failures to relieve symptoms, lead to a high rate of doctor-patient frustration, and deteriorate the relationship. Beside therapeutic failure and drug resistance, the existence of AVD may be caused by sexual reacquisition, nonsexual recurrence, and depressed cellular immunity. Therefore, accurate diagnosis is an important factor in determining therapeutic success of re-treatment, if AVD is persistently occurred.

The approach of women, presenting with vaginal discharge, is not straightforward as that of urethral discharge in men. Infective and/or non-infective conditions often cause symptoms and signs of AVD. Initially, infective causes need to be treated effectively as quick as possible. It is not a simple solution for the management of AVD in the primary healthcare setting; of course, it is not the approach which aims to treat all four infections as a routine method. This would mean unacceptable overtreatment.<sup>33</sup> Local health clinic level, where speculum examination is possible without laboratory facilities, a complete of speculum examination

is recommended. The settings where laboratory supports are available, appropriate investigations will promote the accurate diagnosis. The diagnostic skills, variety of the laboratory tests, depend on a regular performance and accumulation of learning by doing.

The following list provides the whole concerned approach of AVD.<sup>34</sup>

- Symptoms of AVD are only suggestive data. Symptoms alone are not reliable for the diagnosis, while the obvious signs and characteristics of the discharge are partially accurate to make the diagnosis.
- The diagnosis is confirmative evidence, it depends on demonstration of etiological pathogen in single organism conditions such as VC, VT, herpes cervicitis, and gonococcal MPC, or else, bases on clinical diagnostic criteria in multiple organism conditions, for example, BV, chlamydial positive and chlamydial negative form MPC. Not frequently, MPC coexists with vaginitis, particularly BV or VC, whilst BV is always coexisted with VT.<sup>2</sup> The range of diagnosis varies from epidemiological, presumptive, clinical, and definite diagnosis.
- The therapy should include a regimen of at least 95% efficiency for gonorrhea, and at least 85% for other infective conditions, except better regimens are not available.
- Drug acceptability may influence the result of the treatment, and this is due to potential pitfalls of drug administration. Oral drugs are more compliant than injectables. Whereas, single dose and shorter duration are more favorable than longer therapy. In addition, adverse drug effects, and cost of therapy, should be considered as well.
- Prompt treatment for sexual partner(s) of the women with gonococcal MPC, nongonococcal MPC, and VT, prevents the rate of “table tennis phenomenon,” and reduces the transmission of disease, therefore, decreases the frequency of occurrence and adverse sequelae of infection.
- All the patients are recommended to evaluate for the result of therapy. The test of cure is categorized into (i) complete response, the clinical manifestations are relieved and the diagnostic indicators/criteria are negative; and (ii) partial response, the patients are asymptomatic carrier; and (iii) the no response, the clinical manifestations are persisted and the diagnostic indicators/criteria are positive. When test of cure reveals partially response or resistance, re-treatment and retest of cure are required. The coexisting between infective AVD and non-infective AVD can be occurred simultaneously. When the infective causes are eradicated, confirmed by the diagnostic pointers are negative, non-infective condition should be considered if AVD is still persisted.

## HISTORY TAKING

The history taking is initially obtained with three close-ended questions: (i) do you have an excessive vaginal secretion, not associated with menstruation, e.g., occurring every day or nearly every day?; (ii) whether vaginal discharge is associated

with unpleasant odor?; and (iii) whether the discharge is yellowish in color? If the answers are positive in screening questions, concomitant symptoms are then be probed, such as fever, pelvic pain, pelvic discomfort, external and internal dysuria, burning pain of the vulva, perineal/vulvar itching, superficial dyspareunia, redness of the vulva, any lumps or swellings, and ulceration of the perineum. The specific details about the recurrent or resistant infection, previous diagnoses, former treatments and their effects, menstrual history, pregnancy, and sexual practice are inquired.<sup>35</sup>

A rapid onset of AVD suggests an acute infective condition, and secondary to trauma or chemical agents. A gradual onset relates with neoplasms, silent PID, and atrophic vulvovaginitis. Discharge occurring within 24 hours of coitus suggests local trauma, reaction to smegma, and sensitive reaction to barrier method of contraception.

Change of sexual partner and recent multiple sexual contacts are suggestive sexually transmitted infections (STI). Multiple sexual partners in the sexual contact of the patient may also indicate a sexually acquired infection.

Patient's each statement should be given a careful thought as it may point towards diagnosis. For example, premenstrual exacerbation of vaginal discharge points towards VC and TV, repeated antibiotic utilization promotes VC.

## ASSOCIATED SYMPTOMS

External dysuria is limited as pain and burning when urine touches the vulva. Internal dysuria is defined as pain inside the urethra, usually a sign of acute cystitis.<sup>36</sup> Approximately 10% of women with dysuria have vulvovaginitis. External genitalia lesions associated dysuria, usually are characterized as a burning sensation. Dysuria associated AVD is suggestive of LGTI, as well as, a few numbers of urethritis, may atypically present with AVD.

Superficial dyspareunia associates not only coital discomfort, but also the lesions of external genitalia.

Pelvic pain and pelvic discomfort are quite similar, and misleading make clinical correlation difficult. Pelvic pain plays an important role in gynecological conditions, however, the exact relationship between characteristics of pain and gynecological pathology should be analyzed carefully.

Acute pelvic pain that implies to PID is mainly continuous, bilateral, and most severe in the lower quadrants. It frequently increases with movement, Valsalva maneuver, and sexual intercourse. Acute pelvic pain presents for a short duration, less than three week. Acute pelvic pain in PID is less than 15 days in 83% of patients with visually confirmed the disorder. Acute pain mostly occurs within one week in two thirds of patients with gonococcal PID. While the onset of pain in nongonococcal PID occurs steadily throughout the menstrual cycle.<sup>37</sup> A history of prolonged and inconstant pain is not likely to be PID.

Chronic pelvic pain is usually prolonged duration, 6 months or more. The gray zone, between the duration of three weeks to less than six months, may consider as subchronic symptom.

Pelvic discomfort, much more frequent symptom, is generally intermittent, diffuse, and mild intensity in the lower abdomen. Acute and chronic pelvic discomfort can be resulted from LGTI, postoperative adhesions, sequelae of pelvic infection, intrauterine contraceptive device, uterine fibroid, adenomyosis, pelvic relaxation, chronic endometriosis, endometrial polyps. In addition, musculoskeletal, urogynecological, gastrointestinal, and psychological conditions can cause pelvic discomfort as well.<sup>38</sup>

## PHYSICAL AND GENITAL EXAMINATION

General and abdominal should precede the speculum and pelvic examination. Lower abdominal tenderness on abdominal examination is likely related with upper genital tract infections, but not LGTI.

External genital examination is a step to identify genital changes. Close inspection of the external genitalia is useful in looking for atrophic condition, blisters, edema, enlarged lymph nodes, erythema, excoriation, fissure, inflammation, lesions, pallor, papillary structures, thinning, masses, and ulceration.

Speculum examination is not only helpful in inspection of lower genital canal, but also profitable in picking up the endocervical and vaginal secretion. Antiseptic agents should not be applied on the external genitalia before speculoscopy and pelvic examination to avoid vaginal contamination. It leads to false-negative outcome in wet mount preparation for *T. vaginalis* and bacteriological isolation, and false-positive outcome on the pH paper test for alkaline pH.

Warm water provides sufficiency lubrication for speculum insertion. The smallest warm speculum necessary to produce adequate visualization should be the choice. Following insertion, all aspects of vagina and cervix should be inspected under good light source. Particular attention should be paid to vaginal fornices for the lesions such as warts.<sup>39</sup> A very black, tarry type of discharge indicates that there are long-term retention of blood within the genital canal.

The accessibility of uterine cervix provides an opportunity to collect the specimens. The endocervical mucus should be separately collected and examined apart from the vaginal secretion. If cervix is dirty, it should be wiped with a large swab or gauze sponge. The endocervical specimen is then picked up by insertion of a small cotton swab into the endocervical canal.

The term “ectropion” or “ectopy” describes the exposed endocervical columnar epithelium of patulous parous cervix, when the blades of vaginal speculum are separated. Cervical changes over reproductive period and during the menstrual cycle give rise the confusion between actual cervicitis and normal cervix.<sup>40–42</sup> Ectopy or ectropion requires no therapy, in case of absence of visible and microscopic mucopus, and normal colposcopic findings.<sup>19</sup>

Pelvic examination, abdomino-vaginal bimanual palpation, is greatly meaningful in identify local gross anatomical conditions. On pelvic examination, the cervical, uterine, and adnexal tenderness should be based on facial expression of the patients for clues of the patients’ degree of pelvic conditions. The misleading of false-positive tenderness is forceful bimanual examination, and vaginal

discomfort on pelvic examination. So, the cervical tenderness on motion is gently evaluated the mobility, by attempting to displace it anteriorly and posteriorly and from side to side, then the uterus is bimanually palpated. It may be helpful to assess the cervical, uterine, and adnexal tenderness by performing the examination with moving/palpating only one finger of one hand insert into the cervix, posterior, and then both lateral fornices. The other hand with palmar surface mildly presses for evaluation of uterine and adnexal tenderness. If the patient shows a facial expression of pain, with or without specific complaint in one region, it is preferable to start the examination in the different location.

## INVESTIGATION OF ENDOCERVICAL AND VAGINAL DISCHARGE

The endocervical and vaginal specimens are recommended to have macroscopic and/or microscopic examination. Moreover, the laboratory tests vary from the level of peripheral (simple office), intermediate, and advanced laboratory should be performed as appropriate.

### Appearance of Endocervical Discharge

After the ectocervix is wiped clean with a large cotton swab, endocervical mucus is collected on a white-tipped swab, with care taken to avoid contamination by the vaginal secretions. The characteristics of endocervical secretion can be classified into mucoid, cloudy, and mucopurulent. Yellowish color on the white cotton-tipped swab, in contrast to any dark material, is considered as “visible mucopus.”

### Endocervical Smear Stain

The same swab is rolled onto an area of 1–2 square cm, on a microscopic slide. Usually, the smeared secretion is distributed in separated heterogeneous islands, not homogeneous fashion.

The smear is heated dry and stained with methylene blue, safranin or conventional Gram stain. Immersion oil is added, and the microscopic slide is scanned to evaluate the presence and amount of cervical mucus, to look for contaminated squamous cells and microorganisms, and to identify areas of mucus that contain inflammatory cell. Most often, polymorphonuclear (PMN) leukocytes are not uniformly distributed in the cervical mucus, thus, in cases which they are distributed in a patchy fashion. Representative areas containing the dense concentration of such leukocytes are selected. The “microscopic mucopus” is defined as the presence of 10 or more PMN leukocytes per X 1,000 (oil field) on a smear-stained specimen of endocervical mucus at least five separated area.<sup>43</sup> The demonstration of intracellular diplococci, kidney-shaped organism (at least three pairs or more) is strongly suggestive of *N. gonorrhoeae* infection (Fig. 56.1 a and b).

The large surface area of endocervical columnar epithelium may give rise to a large amount of endocervical secretion, typically excessive in mid-cycle. Smear of the mucus with a few leukocytes, suggest physiological endocervical discharge.

\*f+

**Fig. 56.1:** Intracellular diplococci, kidney shapes, and at least three pairs or more is suggestive of *N. gonorrhoeae*. (a) gram stain (oil field). (b) methylene blue stain (oil field).

### Methylene Blue Staining

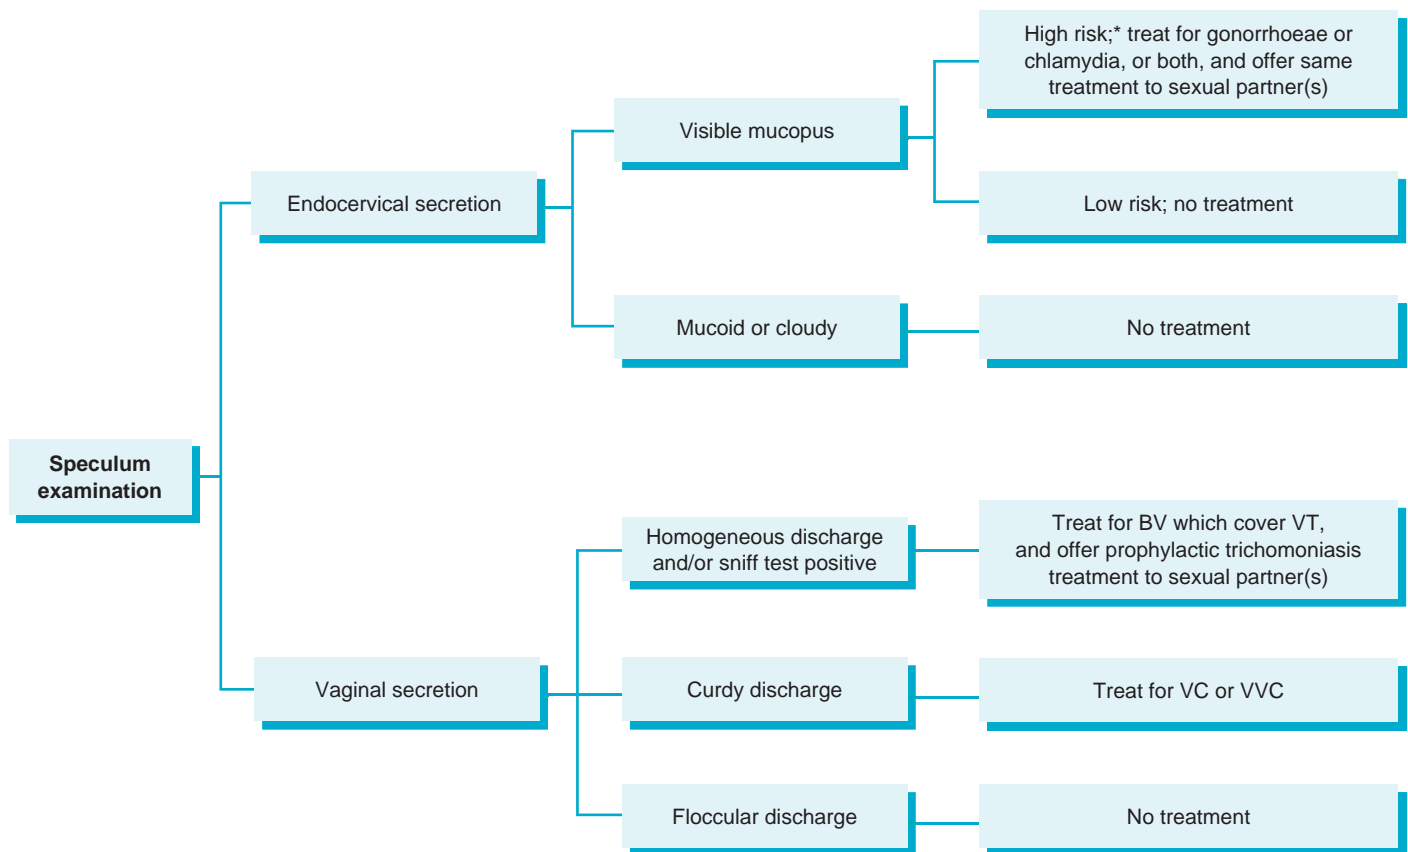

Dissolve 300 mg of methylene blue in 30 ml of ethanol. When the dye is dissolved, add 100 ml of distilled water. Mix the solution and sterilized by filtration (0.22 mm). Keep solution in darkness at 4°C until use.<sup>44</sup> Stain heat-fixed and air-dried smear with covering the slide by the stain for a few seconds. Wash slide under a running tap. Press a blotting paper against the slide and let dry before studying under oil immersion.

### Appearance of Vaginal Discharge

Vaginal secretion is collected from the lower speculum blade. Alternatively, a sterile cotton swab is inserted through the speculum and high vaginal specimen is taken. The characteristic features of the vaginal discharge can be classified into floccular (granular), homogeneous (milky), and curdy (cottage cheese-like) discharge. In pregnant women, the floccular and profuse discharge can be encountered (Figs. 56.2 a, b, c, and d). The sensitivity/specificity/positive predictive value/negative predictive value of characteristics of the discharge are: floccular for no vaginal infection 81/90/86/86%, homogeneous for BV 93/87/81/96, homogeneous for VT 100/59/10/100, homogeneous for BV or trichomoniasis 94/88/84/96%, and curdy for VC 72/100/100/93%, respectively.<sup>2</sup>

Based on macroscopic examination, the management flow chart of AVD can be planned (Fig. 56.3).

**Fig. 56.2:** The variety of vaginal discharge characteristics. (a) Floccular discharge. (b) Floccular and profuse discharge, usually in pregnant women. (c) Homogeneous discharge. (d) Curdy discharge.

\* High risk: prostitutes, persons with multiple sexual partners or a sexual partner with multiple sexual contacts, sexual contacts of persons with culture-proven sexually transmitted infection (STI), and persons with a history of repeated episodes of STI.

Fig. 56.3: Management flow chart of AVD: based on macroscopic examination.

## PERIPHERAL LABORATORY

Peripheral laboratory (simple office analysis) of vaginal secretion includes sniff test, amine test, pH paper test, wet mount preparation, and smear stain. Preceding the amine test, sniff test optionally performs to bypass the amine test in case of positive sniff test.

### Sniff Test

Inhalation of fishy odor, liberated from the speculum blade, is considered as positive sniff test.

### Amine Test

After specimen is taken for wet mount preparation, a drop of 10% KOH is added onto the discharge in the posterior blade of speculum. This is known as speculum amine test. The test is positive when fishy odor is released when a drop of 10% KOH is added onto the discharge in the microscopic slide. The glass slide amine test can be applicable, but less sensitivity.

The fishy odor results from the liberation of amines and organic acids produced by the alkalinization of anaerobic bacteria. A positive amine test is strongly suggestive of BV and VT.<sup>45</sup>

## pH Paper Test

The pH level can be measured by placing a drop of the discharge on a pH paper (short-range pH paper of pH 3.8–5.4, Merck), or whatever commercial pH papers. A high pH of more than 4.5 changes color of the paper from yellow or light green to dark green or deep blue. The result should be interpreted in the following manner: (i) pH 4.5 or less is suggestive of normal discharge or candidiasis; and (ii) pH more than 4.5 is likely to be due to BV or VT. Contamination with cervical mucus must be avoided, as the normal pH of cervical mucus is alkaline. The sensitivity/specificity/positive predictive value/negative predictive values of the pH of more than 4.5 for the diagnosis of BV are 95/72/67/96%.<sup>2</sup>

## Vaginal Wet Mount Preparation

From speculum, an appropriate amount of discharge is transferred separately at two different spots on the same slide for twin wet mount preparation. At one spot a droplet of normal saline is directly added for normal saline wet mount preparation. At the other spot 10% KOH solution is added for KOH wet mount preparation. Both the preparations are covered with a cover slip before immediate scanning under a light microscope. The

preparation should be examined at  $\times 100$  (low power) and then  $\times 400$  (high power) magnification. The substage condenser is kept down and the substage diaphragm is closed to increase the contrast.

The KOH promotes the cell lyses. Hyphae, filamentous elements with branching, are visible as clumps (Figs. 56.4 a and b). Experienced microscopist may occasionally detect budding forms. The detection of hyphae and mycelial filaments has sensitivity of 50–85%.<sup>19,46,47</sup>

Warming the KOH wet mount enhances the cell lysis. By this maneuver, filamentous elements become more clearly visible under microscope, but may lead to completely vaporized specimen.<sup>35</sup> Heat transfer to the site of normal saline wet mount preparation results in immovability of trichomonads. Wet mount preparation with 30% KOH should be avoided, as it also lyses the fungal element and eventually causes false-negative result.

Scanning of several fields for motile trichomonads has a sensitivity of 60–75% and a specificity of up to 99%.<sup>19,48</sup> Sending a “Hanging drop preparation” in 1 ml tube of normal saline solution to microscopic unit should be avoided because it greatly dilutes the concentration of vaginal materials and the collection-examination interval is prolonged. The sensitivity of trichomonad motility is affected in such a preparation. Some clinicians insist for hanging drop preparation; in that case, 0.25 ml saline solution in a tube is more preferable to increase the sensitivity.<sup>44</sup> Our experience

suggested that immediate examination yields results comparable with trichomonal isolation by Cyteine-Peptide-Liver-Maltose (CPLM) medium (unpublished observation).

Clue cell is a squamous epithelial cell with a fuzzy cytoplasm (like shading with black pencil), and cell border is indistinct or stippled rather than (normally seen) finely aligned (Figs. 56.5 a, b, c and d). This appearance is due to massive adherence by a set of BV organisms, *G. vaginalis* and anaerobic bacteria, onto the epithelial cell. If the number of clue cells is more than 20%, of total number of epithelial cells, a diagnosis of BV is suggested. Examination by wet mount preparations provides a sensitivity of 60% and a specificity of up to 98% for the detection of bacterial vaginosis.<sup>49–51</sup> The sensitivity/specificity/positive predictive value/negative predictive values of clue cells more than 20% for the diagnosis of BV are 81/99/97/90%.<sup>2</sup>

Quantitative assessment of lactobacilli is classified as predominant, scanty, or absence of large rod-shaped bacteria. Low number of lactobacilli is strongly suggestive of a diagnosis of BV. The sensitivity/specificity/positive predictive value/negative predictive value of scanty or absence of lactobacilli for the diagnosis of BV are 99/68/65/99%.<sup>2</sup>

These two diagnostic indicators (more than 20% clue cells and scanty or absence of lactobacilli) can be applicable to reproductive-age women but not the postmenopausal women, because of the physiologically decreased lactobacilli and squamous epithelial cell.

When clusters of BV organisms are discovered, they are called as “solid stage”.<sup>19</sup> This feature is seen either in postmenopausal or in reproductive-age. A diagnosis of atrophic vulvovaginitis is suggested if menopausal women have the urogenital symptoms and several signs of vulvovaginal atrophy along with an increased proportion of parabasal cell in wet mount preparation or cytological examination. The wet mount preparation also demonstrates PMN leukocytes and epithelial cells. Normally, the number of leukocytes is not more than epithelial cells. The PMN: epithelial cell ratio more than 1:1 could be either infective (e.g., MPC, VT) or non-infective condition (e.g., inflammatory and necrotizing process, late proliferative phase of the cycle). The sensitivity/specificity/positive predictive value/negative predictive values of PMN leukocytes: epithelial cell ratio more than 1:1 for the diagnosis of *N. gonorrhoeae* and *C. trachomatis* infections are 64/71/10/98%.<sup>2</sup>

### Vaginal Smear Stain

Vaginal smear stained with methylene blue, safranin, or Gram stain, can be used in place of the wet mount to detect predominant bacterial flora, clue cells, leukocytes, epithelial cell, and PMN: epithelial cell ratio, but not helpful for detecting trichomonads.

Based on macro/microscopic examination and peripheral laboratory, the management flow chart of AVD can be planned (Fig. 56.6).

### Individual Entities

#### MUCOPURULENT CERVICITIS

Trichomonad, *Candida*, and herpes simplex virus can cause inflammation of the ectocervix, ectocervicitis. Cervical

**Fig. 56.4:** KOH wet mount preparation (lower power field). (a) squamous vaginal epithelial cells, leukocytes, are lysed by 10% KOH and reveals clear cell background in the absence of hyphae. (b) hyphae (filamentous bodies) of *Candida*.

involvement of recurrent herpes apparently produces the multiple superficial ulcers. *N. gonorrhoeae* and *C. trachomatis* infect only the glandular epithelium, and are responsive for gonococcal and nongonococcal mucopurulent cervicitis (MPC).<sup>52</sup> Few studies,

*C. trachomatis* related to MPC has discovered in the range of 34.1–39%.<sup>53,54</sup> Roughly, at least one half of MPC is caused by *N. gonorrhoeae* and *C. trachomatis*.<sup>43</sup>

## Diagnosis

History of yellowish discharge is an indication toward the diagnosis of MPC. The diagnosis of MPC is based on clinical diagnostic criteria, of both visible mucopus and microscopic mucopus, the modified criteria.<sup>2</sup> Visible mucopus is considered when yellowish color is recognized on a white cotton-tipped swab, whereas, microscopic mucopus is reflected by the presence of 10 or more PMN leukocytes per oil field, at least five separate areas. MPC is disregarded and the patient needs to be re-evaluated if vaginal contamination in the specimen (Figs. 56.7 a and b). The vaginal contamination can be confirmed by: (i) more than 100 cells vaginal epithelial cells per slide, and (ii) vaginal flora more than 100 bacteria per oil field.<sup>43</sup> Positive identification of *N. gonorrhoeae* in smear or culture confirm gonococcal MPC. Nongonococcal MPC is classified into two categories depending on the chlamydial identification—chlamydia positive and chlamydia negative form.<sup>53</sup>

For MPC, the sensitivity/specificity/positive predictive value/negative predictive values of macroscopic and microscopic findings are as under: visible mucopus 36/86/11/97%, microscopic mucopus 64/69/9/98%, both visible and microscopic mucopus 36/87/12/97%, and visible or microscopic mucopus 64/71/10/98%, respectively.<sup>2</sup>

## Treatment

The therapy depends mainly on the isolation of the causative agent or clinical/microscopic findings. If *N. gonorrhoeae* is positive, a treatment regimen for uncomplicated gonorrhea (effective against penicillinase-producing *N. gonorrhoeae*) is recommended.<sup>55</sup> For nongonococcal MPC, either chlamydia positive or Chlamydia negative form, any regimen effective against *C. trachomatis* is preferable (Table 56.2). The same regimen should be prescribed to sexual partner(s). In pregnant women, MPC with negative identification of *N. gonorrhoeae* and *C. trachomatis* needs no treatment.

*C. trachomatis* probably co-infects with *N. gonorrhoeae*, and *vice versa*. Thus, epidemiological treatment of both organisms is considered in the areas of high prevalence of both pathogens.

In our experience, doxycycline, minocycline and ofloxacin are satisfactory for the treatment of MPC. In a trial with doxycycline (200 mg initially, followed by 100 mg twice daily for 8 days), the clinical assessment was satisfactory in 92.8%, the visible mucopus has disappeared in 86.8%, and the number of PMN leukocytes was reduced in 71.4% after completion of the treatment.<sup>56</sup>

Similarly, with minocycline (100 mg twice daily for 7 days), the clinical assessment was satisfactory in 94.8%, the visible mucopus has disappeared in 67.2%, and the number of PMN leukocytes was reduced in 51.7% after completion of the treatment. A wide variety of adverse drug events occurred; nausea, vomiting,

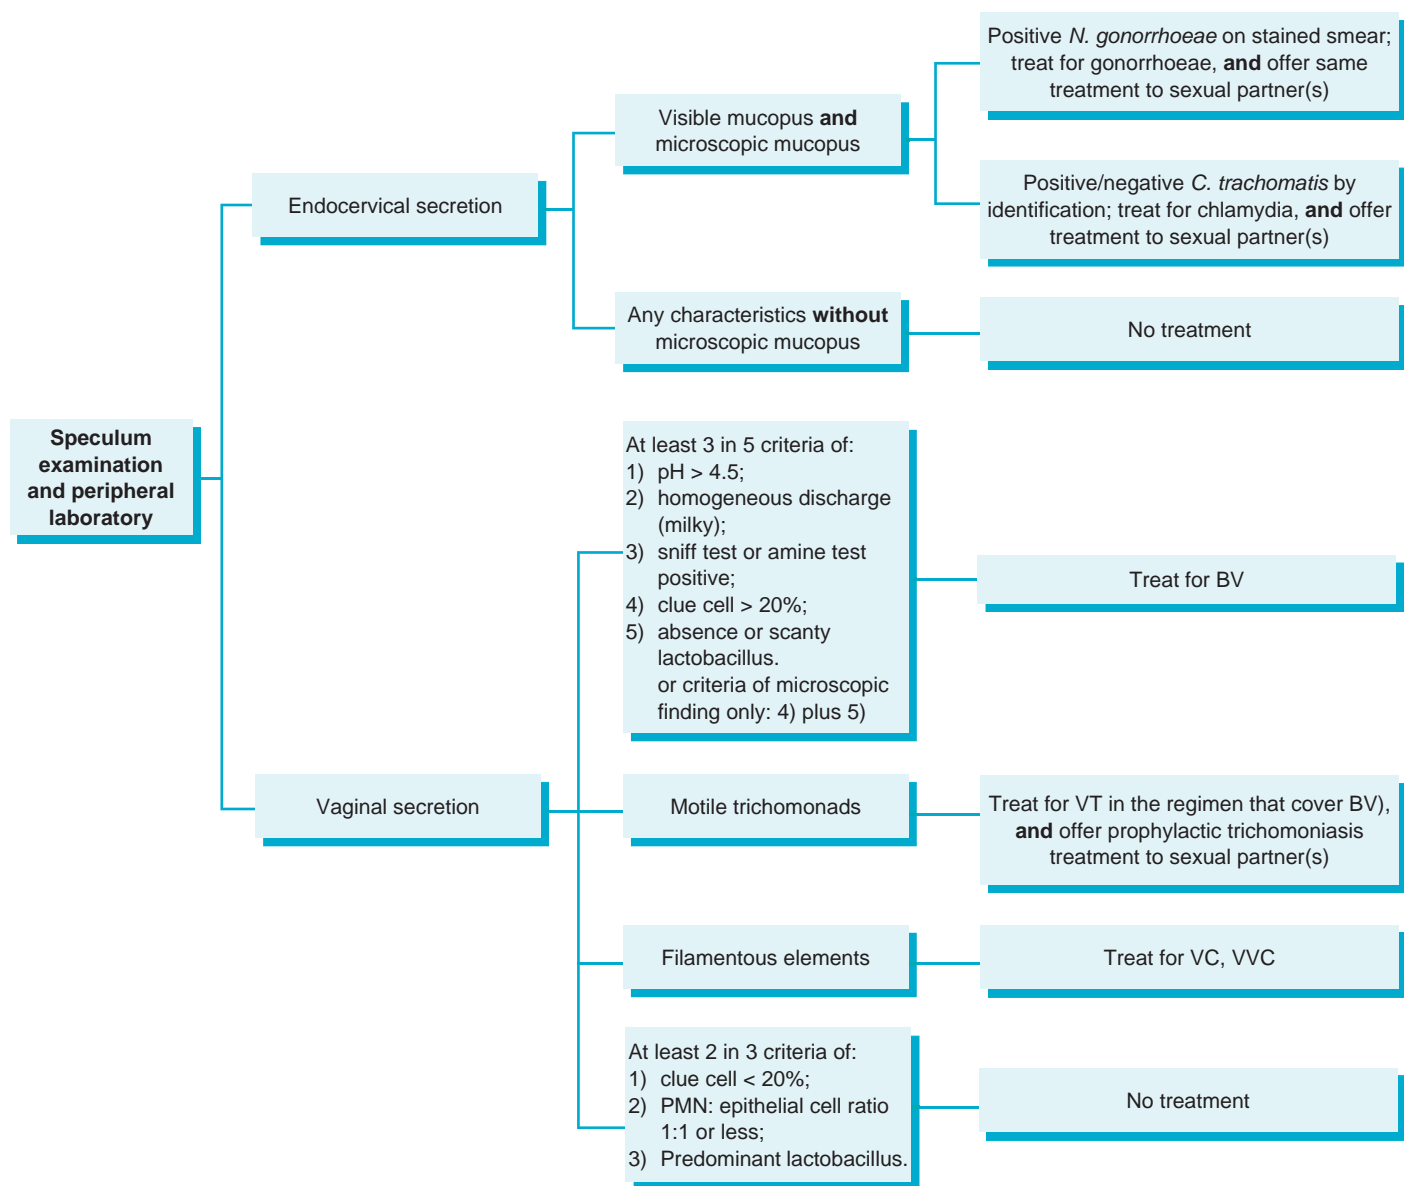

Fig. 56.6: Management flow chart of AVD: based on macro/micro examination and peripheral laboratory

\*c+

\*d+

Fig. 56.7: Methylene blue stain of endocervical smear ( $\times 1000$ ). (a) Microscopic mucopus; polymorphonuclear leukocytes more than 10 per oil immersion field in at least five representative areas, is diagnostic. (b) Heavy contamination by vaginal epithelial cells and flora is undesirable.

**Table 56.2:** Treatment of Gonococcal and Nongonococcal MPC

Disease	Regimens	
	Agent	Dosage
Gonococcal MPC	Ciprofloxacin*	500 mg orally in a single dose
	Ceftriaxone	250 mg intramuscularly in a single dose
	Cefixime	400 mg orally in a single dose
	Ofloxacin†	400 mg orally in a single dose
	Azithromycin*	2 g orally in a single dose
Nongonococcal MPC	Doxycycline*	100 mg orally twice daily for at least 7 days
	Minocycline†	100 mg orally once daily for at least 14 days
	Tetracycline†	500 mg orally, four times a day for at least 7 days
	Ofloxacin†	200–400 mg orally twice daily for at least 7 days
	Erythromycin stearate	500 mg orally, four times a day for at least 7 days
	Azithromycin*	1 g orally, single dose

\* Should only be given during pregnancy when need has been clearly identified.

† Established contraindication in pregnancy.

dizziness, and hyperpigmentation of oral mucosa.<sup>57</sup> When minocycline regimen was adjusted to 100 mg daily for 14 days, the clinical assessment was satisfactory in 91.4%, the visible mucopus has disappeared in 100%, and the number of PMN leukocytes was reduced in 85.7% after completion of the treatment. The adverse drug events were minimized.<sup>58</sup>

With ofloxacin (100 mg twice daily for 10 days), complete and partial responses are achieved in 66.7% and 27.8%, respectively of the patient with chlamydia positive MPC. This was not quite different from the patients with chlamydia negative form MPC with 68% complete and 32% partial response. Ofloxacin, 200 mg twice daily for 7 days produced comparable results.<sup>53</sup> Azithromycin, 1 g orally single dose can be considered as second line drug when the conventional treatments fail.<sup>55</sup>

Visible and microscopic mucopus in asymptomatic patients is apparently relates to the menstrual cycle. When AVD is relieved it is not necessary to provide the treatment to eradicate the mucopus, except when the upper genital tract infection is suspected. Uterine tenderness is suggestive of silent PID, while cervical and adnexal tenderness is correlated with overt PID. Further investigation includes endometrial sampling, clinical diagnostic criteria for PID, and eventually laparoscopy. Treatment of PID principally covers three main organisms, *N. gonorrhoeae*, *C. trachomatis*, and anaerobic bacteria.

Re-treatment for nongonococcal MPC is recommended if the test for cure reveals no response. When AVD persists without visible or microscopic mucopus, non-infective causes should be considered.

## BACTERIAL VAGINOSIS

Bacterial vaginosis (BV), formerly known as nonspecific vaginitis, has a poorly understood pathophysiology and is asymptomatic in up to 50% of women. Overgrowth of BV organisms results in the development of symptoms of excessive vaginal secretion and malodorous discharge. Many women complain of foul smell immediately after unprotected sexual intercourse. This is due to mixing of the discharge with alkaline semen, producing the aromatic amine.

## Diagnosis

Symptoms alone are not reliable for the diagnosis of BV. The diagnosis is based on a diagnostic criteria of clinical and laboratory indicators as follow:<sup>49,59</sup>

1. The vaginal pH greater than 4.5;
2. Homogeneous and thin discharge (milky discharge);
3. Positive sniff/amine test;
4. Clue cell greater than 20% of total vaginal epithelial cells;
5. Scanty or absence lactobacilli

Diagnosis of BV can be made if the patient fulfils 3 of 5 indicators.

One should be cautious that sexual intercourse within a few days can result in homogenous discharge, and seminal fluid may raise the vaginal pH to alkaline. In that case, the clinical diagnosis of BV should be made mainly on the basis of the wet mount preparation. The modified criteria of microscopic findings include the combined criteria of (i) clue cell greater than 20% of total vaginal epithelial cells; and (ii) scanty or absence lactobacilli. This can be applied in the settings that only microscopic examination is available.

BV needs to be treated only when the patient fulfills of diagnostic criteria. The issue regarding treatment of asymptomatic cases or low-risk pregnant women with BV remains unresolved. The secondary preventive screening and treatment of both symptomatic and asymptomatic cases of BV before reproductive tract surgery is recommended.

## Treatment

Erythromycin and doxycycline have not been found effective for treatment of BV.<sup>60,61</sup> Metronidazole and other 5' nitroimidazoles are effective drugs in treatment of BV. Treatment of male sex partner(s) with metronidazole has no benefit in the preventing of recurrent BV.<sup>62</sup> The facultative flora of vagina, Lactobacilli are resistant to metronidazole. VC may develop in only a small numbers of women treated with metronidazole. Metronidazole has been found to be carcinogenic in rodents. The efficacy of metronidazole must be weighed against its potential toxicity. It must be avoided in pregnant women, especially in first trimester.

Metronidazole, 500 mg orally twice daily for 7 days, has cure rates for BV in the range of 92–100%.<sup>63–65</sup> Two grams of

tinidazole, a double dose of 48 hours apart, has produced cure in about.<sup>65</sup> In another study, nimorazole 500 mg orally twice daily for 7 days, cured about 90%.<sup>59</sup> Clindamycin, 300 mg orally twice daily for 7 days, produced complete response in 94.5%, and partial response in 5.5%.<sup>66</sup>

In summary, oral metronidazole is a preferable treatment for BV with dramatic response. Other effective agents include tinidazole, nimorazole, and clindamycin, can be used if the patient is unable to tolerate metronidazole. Complete response to treatment often rules out drug resistance. If the first test of cure reveals partial response or no response, possibility of resistance and persistence of infection should be considered. Such patients should be treated with antimicrobial agent of a different group.

### VAGINAL AND VULVOVAGINAL CANDIDIASIS

Genital infection with *Candida* can result in either vaginal candidiasis (VC) or vulvovaginal candidiasis (VVC). More than 50% of women older than 25 years, have had one episode of vulvovaginal candidiasis,<sup>67</sup> but fewer than 5% of these women experience recurrent infection.<sup>68</sup> Generally, *Candida* is not transmitted sexually and episodes of VC/VVC seem unrelated to the number of sexual partners.<sup>68,69</sup> Treating the male partner is unnecessary unless he has balanitis and balanoposthitis.<sup>9</sup>

VC/VVC occurs more frequently in pregnant women, and its incidence increases with gestational age. It usually does not pose serious problems to the mother and the newborn, although the symptoms can be distressing. The disease in mother often clears up spontaneously after delivery. Women with VC/VVC may be asymptomatic or may present with complaints of mild to severe degree of itching, discharge, pain, swelling, erythema, edema, and ulceration. The most severe infection often occurs in pregnant women who are diabetics.

### Diagnosis

Examination demonstrates erythema, inflammation, and an adherent discharge described as “cottage cheese-like”. Establishing *Candida* species as the cause of organisms is difficult, because as many as 50% of asymptomatic women, as part of their endogenous vaginal flora.<sup>68</sup> So, the diagnosis of VC is established only when hyphae are detected on KOH wet mount preparation. Other characteristics suggesting VC include a vaginal pH less than 4.5 and a lack of odor in the discharge.

There is evidence that the inflammation of VC is immunologically mediated as in symptomatic women, only small numbers of fungus is present.<sup>70</sup> The diagnosis of VC should never be made when hyphae are absent. Isolation of *Candida* through culture can be undertaken in patient with no demonstrable hyphae but presence of mixed clinical symptoms such pruritus, erythematous vulvar rash, vulvar fissure, or white vulvar plaque.<sup>71</sup> Occasionally, yeast forms can be detected by Papanicolaou smear or fungal isolation. It is not necessary to treat the yeast form. In

those cases but the hyphae do. In those cases, the patient should be re-evaluated. When the KOH wet mount preparation reveals hyphae element, therefore, VC/VVC treatment is indicated.

### Treatment

Topical polyene such as nystatin, 100,000 units, intravaginally daily is well-tolerated and inexpensive, but requires continuous therapy for 2 weeks, which may affect patient compliance. The cure rate is in the range of 50–80%.<sup>9</sup> Topical polyenes have been largely replaced by topical azoles, in the treatment of VC even in the pregnant women, as first-line drug. Now, topical and oral azoles are available in a variety of formulations. The average cure rate of topical azoles is in the range of 80–90%. Oral azoles achieve comparable or marginally higher therapeutic cure.<sup>19,72</sup> The oral agents, however, do not provide immediate relief of local symptoms, hence severe vulvar symptoms may necessitate adjunct topical treatment for the first few days.

After adequate the local therapy azole, persistent infection is considered, if the first test of cure reveals partial response or no response suggested by detection of hyphae. In such patients re-treatment should be considered either different local therapy with a different azole, or the combination of local and oral azoles, as the second-line therapy.

Recurrent VC/VVC is distinguished from persistent infection by the presence of a symptom-free and pathogen-free interval. Recurrent VC is considered when, following complete response, at least three episodes unrelated to antibiotic therapy occur within one year.<sup>73</sup>

In the patient with recurrent infections, the risk factors should be eliminated. In VC/VVC recurring after complete cure with adequate treatment, prophylactic therapy should be initiated. A short course of local or oral azole for 5 or 6 days, is administered in the week before next cycle of menstruation for three consecutive cycles is an effective prophylactic regimen to reduce the rate of recurrence. If necessary, the isolation of *Candida* through culture may be helpful in identify other less common species of *Candida*.

### VAGINAL TRICHOMONIASIS

A strawberry cervix, demonstrating typical epithelial hemorrhages is considered as a presumptive diagnosis of vaginal trichomoniasis (VT), however this characteristic sign is seen only in about 2% of the patients with VT.<sup>74</sup> Strawberry cervix is a sign of advanced trichomoniasis, hence is becoming rarer in the present era due to early diagnosis and treatment.

### Diagnosis

The presence of *T. vaginalis* correlates poorly with symptoms and signs in women,<sup>75,76</sup> the diagnosis of trichomoniasis, therefore, depends on detection of motile protozoan (Figs. 56.8 a and b). BV always coexists with VT infection. On the other hand, VT co-infection with VC is rare, only in optimized vaginal pH

conditions. VT is considered as a STI, although only about 30% of male sexual partners of infected women have positive urine isolation. Most men are asymptomatic.<sup>77</sup>

## Treatment

Women with VT can be treated with metronidazole 2 g given orally as single dose, along with treatment of partner(s) in the same dose. This regimen is moderately effective with cure rates in the range of 82–88%.<sup>78</sup> More preferable regimen is metronidazole 500 mg orally twice daily for 7 days, along with treatment of partner(s) with 2 g orally.<sup>2,79</sup> This regimen not only provides higher cure rates, but also cure concomitant BV. Optionally, other 5' nitroimidazoles can also be applied.

Metronidazole, like disulfiram, blocks hepatic metabolism of ethanol to aldehyde intermediaries, which produce a variety of systemic symptoms including nausea and flushing. Patients should be cautioned about consumption of alcohol while on treatment. According to a recent meta-analysis, the single 2 g dose of oral metronidazole can be used safely in any trimester of pregnancy.<sup>80</sup>

The test of cure is recommended in every case to make clear whether the result of the treatment is complete, partial or no response. Recovery of pathogen and diagnostic criteria after completion of

therapy is considered as either re-infection from the partner(s) or failure of the therapy. To achieve the complete response, the management includes partner's assessment and re-treatment with and other 5' nitroimidazoles. If this also fails, then the combination of vaginal and oral 5' nitroimidazoles are recommended.<sup>81</sup>

## NON-INFECTIVE LEUKORRHEA

Most infectious causes may be included or excluded by standard basic investigation. Non-infective leukorrhea (NIL) should be considered as the diagnosis in women with AVD when following criteria are fulfilled:<sup>2</sup>

### Endocervical secretions

- Absence of visible mucopus,
- Absence of microscopic mucopus,

### Vaginal secretion

- Absence of trichomonad motility,
- Absence of filamentous elements,
- Clue cell less than 20% of total vaginal epithelial cells,
- Numerous lactobacilli,
- PMN leukocytes: epithelial cell ratio is 1:1 or less

If all seven criteria are fulfilled, vaginal and cervical infections can be safely excluded.<sup>2</sup> In NIL, the striking microscopic findings in vaginal secretion are of an abundance of large rods and normal vaginal epithelial cells (Figs. 56.9 a and b). The coincident findings include a small number of leukocytes and clue cells less than 20% of total vaginal epithelial cells. Other suggestive findings are absence of both trichomonad motility and hyphae. Cervix does not show visible or microscopic mucopus.

Women with prominent discharge with no any abnormal findings on basic investigation should be considered to be cases of NIL. The perineal hygiene care should be strongly advised to practice. With this, AVD is relieved or alleviated in majority of the cases. In a study of 70 patients with NIL, 48 (68.5%) improved with perineal hygiene care, while, 22 (31.4%) persisted of excessive vaginal secretion and/or yellowish discharge. Among 22 patients with persistent AVD, test of cure was categorized. First group of 12 (54.5%) patients had persistent NIL. These patients were evaluated for other non-infective causes responsible for altered vaginal flora, and physiologically changes. These conditions include smegma reaction, reaction to barrier contraceptives, vaginal douches, sexual arousal, pattern of sexual practices, and change of sexual partner(s), etc. Second group of 9 in 22 (40.9%) patients comprised of 1 case with MPC and 8 cases with either visible or microscopic mucopus. MPC case requires re-evaluation and re-treatment, while the remaining 8 cases needed further evaluation and investigations. Third group of 1 (4.5%) patient had late development of BV, treated accordingly.<sup>2</sup>

## Perineal Hygiene Care

The female sex organs are more complex than those of the male. The location of external urethral meatus, introitus of the vagina, and the opening of anal, are adjacent to each other and this may result in

**Fig. 56.8:** Normal saline wet mount preparation. (a) Squamous vaginal epithelial cells, numerous leukocytes, ovoid body slightly larger than leukocyte (lower power field). (b) Ovoid body of trichomonads (high power field), motility is suggestive of trichomoniasis.

\*c+

\*d+

**Fig. 56.9:** Normal saline wet mount preparation. (a) Squamous vaginal epithelial cells (intermediate cell), and numerous lactobacilli (lower power field). (b) Squamous vaginal epithelial cell, and numerous of thin rods (high power field).

a vaginal ecosystem contaminated with bacteria mainly from feces and urine. Cleanliness around the external genitalia is important. Following instructions should be given to the patients: when there is an infection resulted from lower genital tract, to avoid the change of vaginal ecosystem. Suggestions for practice are as follow:<sup>34</sup>

- After bath, defecation, and sexual intercourse, always wash the area with water and dry it thoroughly before putting on underwear.
- After defecation, wipe and wash from front to back (from vagina to anus) to avoid fecal contamination of vagina.
- In hot weather causing too much perspiration, the underwear should be changed more frequently. A wet underwear produces smell and itching. An irresistible urge to scratch can in turn cause rashes and abrasion.
- Avoid wearing nylon and rayon underwear, as they cause more sweating than cotton underwear. The underwear with cotton component at least 60–80% is suggested, especially those allergic to synthetic materials.
- The underwear should be sun or heat-dried to remove all the moisture.

- In some circumstances soft stool may stain the underwear. In that case, the underwear should be changed immediately.
- The vagina should not be spray-washed. It may carry bacteria from the vagina into the intrauterine cavity. If necessary, the vagina can be cleaned with fingers. The fingernails should be kept trimmed to avoid risk of trauma.
- Vaginal douching with antiseptics is unnecessary and it may damage the vaginal epithelium. At times, patient may be allergic to the antiseptics.
- The tampon should be changed frequently. When the diaphragm is used, it should not be left in the vagina longer than the recommended period.

## Introduction

The symptom of lower abdominal pain in women is a common one and may occur in a large number of conditions including disorders of the bladder, bowel, musculoskeletal system, and the female reproductive organs.

An important cause of lower abdominal pain in women is pelvic inflammatory disease (PID). PID is defined as infection of the female genital tract above the internal os of the cervix. This implies endometritis, salpingitis, salpingo-oophoritis, tubo-ovarian abscess, and pelvic peritonitis. PID is caused by bacterial infection ascending from the cervix. The bacterial pathogens that cause PID are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and anaerobic and aerobic bacteria.<sup>1,2</sup> The majority of women with gonococcal or chlamydial infection of the cervix have no symptoms at all. When symptoms do occur, they may be related to complications such as PID. PID is an important health problem, as it can lead to death as a result of ruptured pelvic abscess, pelvic peritonitis, and ruptured ectopic pregnancy, and it can lead to sub-fertility or infertility.<sup>1</sup>

Women with PID usually present with lower abdominal pain, but this is a common symptom and not all women with lower abdominal pain have PID. Women with other potentially life-threatening conditions such as ectopic pregnancy, appendicitis, pelvic abscess or complications of pregnancy such as incomplete abortion, septic incomplete abortion, and puerperal sepsis may also present with lower abdominal pain. Women with PID may also have other symptoms such as menstrual problems, vaginal discharge, dyspareunia, fever, diarrhea, and even vomiting.<sup>3-5</sup>

In order to make a diagnosis of PID, a detailed history should be taken and the patient should be examined carefully. From the history and examination, it is possible to identify those women with lower abdominal pain who may have a surgical or obstetric complication requiring immediate referral to a hospital for specialist attention. The following symptoms and signs are suggestive of PID:

- History of lower abdominal pain, vaginal discharge, irregular menstruation, and fever.
- Pain and tenderness in the pelvis detected on abdominal palpation.

- Cervical excitation tenderness detected by digital vaginal examination.
- Depending on the severity of the condition, signs of septicemia may also be present, and the patient may be extremely ill and toxic.

## Clinical Criteria for Referring Women with Lower Abdominal Pain for Specialist Attention

Since lower abdominal pain in women may be caused by a large number of conditions, it is important that a thorough assessment be carried out so that patients with serious conditions and complications are provided with adequate care, including referral for specialist opinion. The following features in the history are indicative of a gynecologic problem requiring immediate gynecologic attention<sup>6</sup>:

- History of a missed or delayed period, or that a period is overdue—this is suggestive of a pregnancy complication or ectopic pregnancy.
- History of abortion within the preceding 6 weeks suggestive of incomplete abortion or septic incomplete abortion.
- History of a delivery or miscarriage within the preceding 6 weeks—suggestive of a complication following parturition, such as retained products of conception or pelvic sepsis.
- History of irregular heavy vaginal bleeding—suggestive of incomplete abortion, retained products of conception or placental tissue, or dysfunctional uterine bleeding.

From the examination, the following features are indicative of a surgical or gynecologic complication requiring specialist opinion:

- Abdominal guarding and rebound tenderness—suggestive of peritonitis, intra-abdominal bleeding, or intra-abdominal abscess.
- On abdominal palpation, a mass is found—suggestive of an abscess, ovarian cyst, fibroid, or tumor.
- Active heavy continuous vaginal bleeding—suggestive of a pregnancy complication.

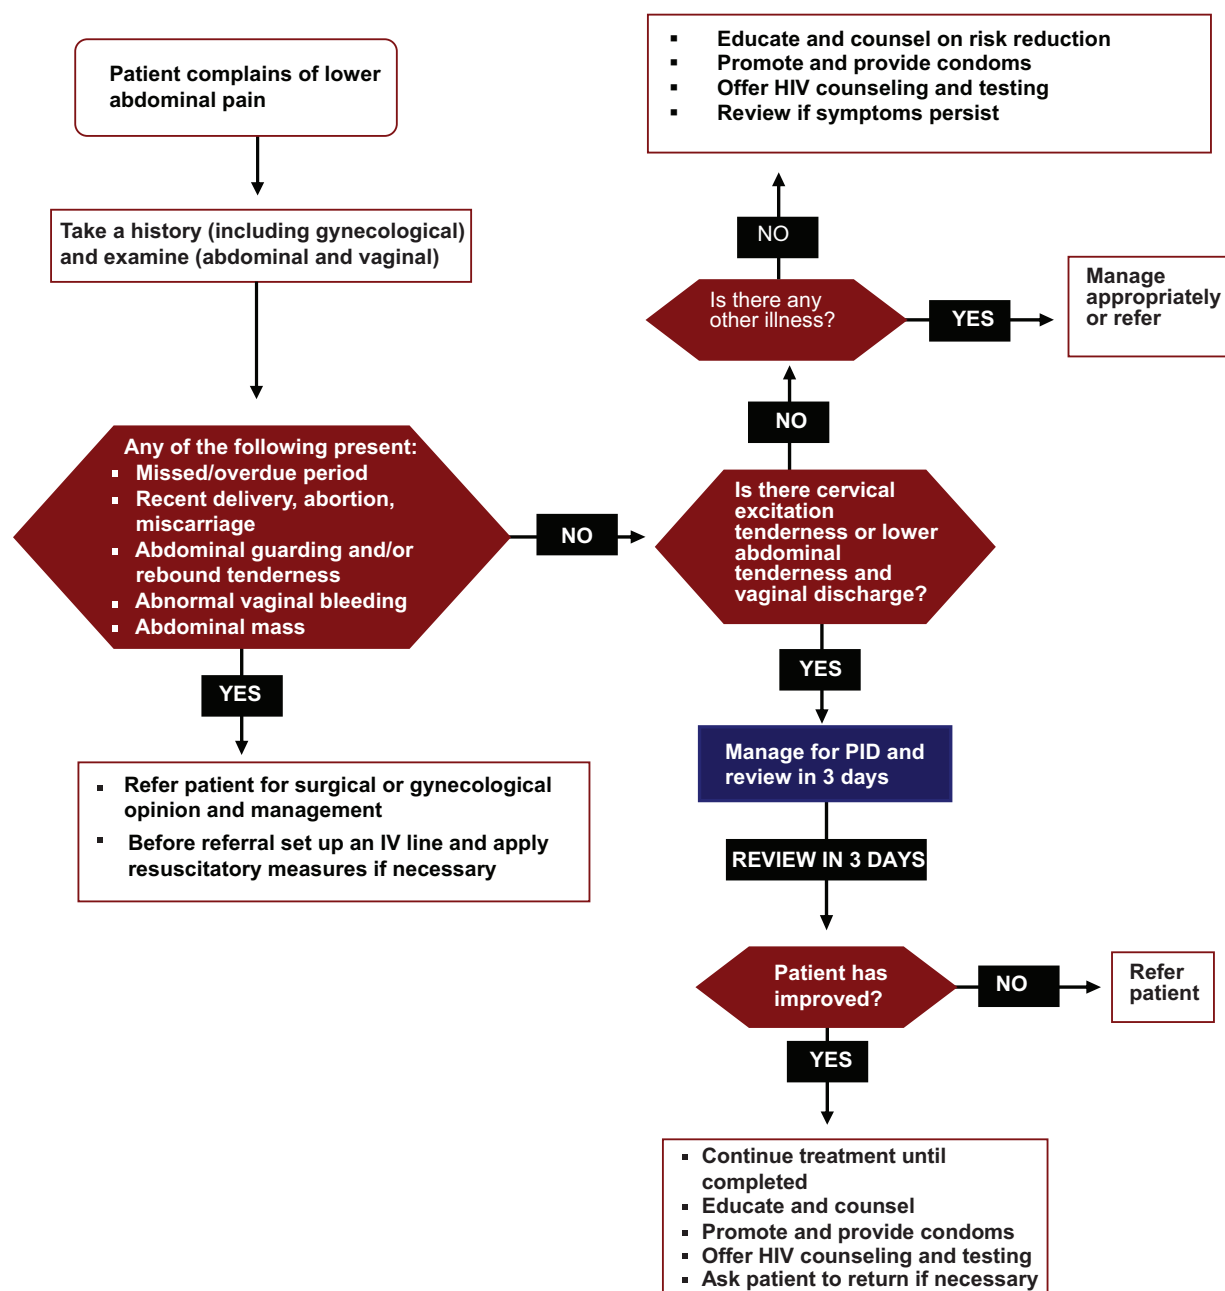

**Table 57.1:** Symptoms and Signs Indicative of a Surgical or Gynecological Problem Requiring Immediate Referral for Specialist Attention

Symptoms	Signs
Missed, overdue, delayed period	Abdominal guarding and/or rebound tenderness
Recent abortion, delivery or miscarriage	Abdominal mass
Metrorrhagia	Active vaginal bleeding

Table 57.1 summarizes the referral criteria for women with lower abdominal pain.

### Management of Lower Abdominal Pain in Women

As the main causes of PID include gonococcal, chlamydial, and anaerobic bacterial infection, all women who have PID should be treated for these infections initially. The flowchart in Figure 57.1 gives guidance on the syndromic management

**Fig. 57.1:** Flowchart for the management of lower abdominal pain in women.

of lower abdominal pain in women. The flowchart may be summarized as follows:

- In all women with lower abdominal pain, a history should be taken and a careful examination should be carried out.
- From the history, the following information should be obtained: has the patient missed a period, has there been a delayed period, or has a period been overdue, is there a history of an abortion or delivery in the preceding six weeks; or is there a history of irregular heavy vaginal bleeding.
- When examining the patient, look specifically for the following:
  - Is there abdominal guarding or rebound tenderness?
  - Is a mass palpable in the abdomen?
  - Is there vaginal bleeding?
- If none of the above referral criteria are present and the patient has vaginal discharge and/or cervical excitation tenderness, then the most likely diagnosis is PID. This patient must be treated for PID as described below and should be reviewed in 3 days time or sooner if symptoms are not improving or if she is feeling worse. On review in 3 days if she is improving then continue treatment for a total of 14 days.

## Treatment of PID

The patient with PID should be treated for gonococcal, chlamydial, and anaerobic bacterial infection. The following recommendations are made: All patients should be treated for gonococcal, chlamydial, and anaerobic bacterial infections. Patients treated on an outpatient basis should be reviewed 72 hours after starting treatment or sooner if their symptoms become worse. At the 72-hour review, if patients are not improving then they should be referred for specialist (surgical or gynecological) opinion. If they are improving, then treatment should be continued for a total of 14 days. Intrauterine contraceptive devices should be removed after starting therapy.

### TREATMENT ON AN OUTPATIENT BASIS (Box 57.1)

- Single-dose therapy for uncomplicated gonorrhea (i.e., ceftriaxone 250 mg IM or ciprofloxacin\* 500 mg PO), PLUS
- Treatment for chlamydial infection with doxycycline 100 mg orally twice daily for 14 days, PLUS
- Treatment for anaerobic bacterial infection with metronidazole, 500 mg orally, twice daily for 14 days.

#### Box 57.1 Outpatient Therapy for Pelvic Inflammatory Disease

- Ceftriaxone 250 mg IM OR Ciprofloxacin\* 500 mg by single oral dose, PLUS
- Doxycycline 100 mg orally twice daily for 14 days, PLUS
- Metronidazole 500 mg orally twice daily for 14 days

**Note:** Review the patient in 72 hours after starting treatment and if she has improved continue treatment; if she has not improved refer her to a health facility where specialist surgical and gynecological opinion may be obtained.

\*Quinolones are no longer recommended for gonococcal infection in Asia.

Review the patient in 72 hours time and refer her if she is not improving or continue treatment if she is improving.

#### Notes:

1. Patients taking metronidazole should avoid taking alcohol.
2. Ciprofloxacin and other quinolones are no longer recommended for treatment of gonorrhoea in Asia. Quinolones are contraindicated during pregnancy and lactation.
3. The intrauterine contraceptive device (IUCD) is a possible risk factor for the development of PID. It is recommended that the IUCD be removed soon after antimicrobial therapy for PID is commenced. When an IUCD is removed, contraceptive counselling is necessary.
4. All patients treated on an outpatient basis should be reviewed 72 hours after commencing treatment. If the patient is not improving, then she should be admitted or referred for admission and for specialist opinion and management.

### INPATIENT TREATMENT (Box 57.2)

Acute PID may be a life-threatening condition, as it can lead to the development of intra-abdominal abscesses and peritonitis. Patients may develop septicemia and septic shock. Bowel fistulae are also known to occur during this time. Therefore, women who have PID and also signs of tubo-ovarian abscess or pelvic and generalized peritonitis need to be referred for inpatient management. In addition, women with lower abdominal pain in whom a surgical cause cannot be ruled out and women in whom a complication of pregnancy such as, threatened, incomplete or septic abortion, and retained products of conception, need to be referred for specialist opinion.

For patients hospitalized with acute PID, any of the following three regimens may be used:

#### Regimen 1:

- Treatment for gonococcal infection with ceftriaxone 250 mg intramuscular daily for at least 2 days after the patient has improved, PLUS
- Treatment for chlamydial infection with doxycycline, 100 mg orally twice daily, or tetracycline, 500 mg orally, 4 times daily for 14 days, PLUS
- Treatment for anaerobic bacterial infection with metronidazole, 400 mg (or 500 mg) orally, twice daily for 14 days.

#### Regimen 2:

- Clindamycin 900 mg IV every 8 hours for at least 2 days after the patient has improved, PLUS
- Gentamicin 1.5 mg/kg IV 8 hourly for at least 2 days after the patient has improved, FOLLOWED BY
- Doxycycline 100 mg orally twice daily or tetracycline 500 mg orally 4 times daily for 14 days, AND
- Metronidazole 500 mg orally or by intravenous injection, twice daily for 14 days.

#### Regimen 3:

- Ciprofloxacin\* 500 mg orally twice daily for at least 2 days after the patient has improved, PLUS
- Doxycycline 100 mg orally twice daily or tetracycline 500 mg orally 4 times daily for 14 days, PLUS

**Box 57.2** Inpatient Therapy for Pelvic Inflammatory Disease**Regimen 1:**

- Ceftriaxone 250 mg by intramuscular injection daily for at least two days AFTER the patient has improved, PLUS,
- Doxycycline 100 mg orally twice daily for 14 days (or, Tetracycline 500 mg orally 4 times a day for 14 days), PLUS,
- Metronidazole 400 mg (or 500 mg) orally twice daily for 14 days

**Regimen 2:**

- Clindamycin 900 mg by intravenous injection every 8 hours for at least 2 days AFTER the patient has improved, PLUS,
- Gentamicin 1.5 mg/kg intravenously every 8 hours for at least 2 days AFTER the patient has improved FOLLOWED BY
- Doxycycline 100 mg orally twice daily for 14 days (or, Tetracycline 500 mg orally 4 times a day for 14 days), PLUS
- Metronidazole 400 mg (or 500 mg) orally twice daily for 14 days

**Regimen 3:**

- Ciprofloxacin 500 mg orally twice daily for at least 2 days AFTER the patient has improved, PLUS,
- Doxycycline, 100 mg orally twice daily, or tetracycline, 500 mg orally, 4 times daily for 14 days, PLUS,
- Metronidazole 400 mg (or 500 mg) orally or by intravenous injection, twice daily, OR,
- Chloramphenicol, 500 mg orally or intravenously injection, 4 times daily

- Metronidazole 400 mg (or 500 mg) orally or by intravenous injection, twice daily.

**Notes:**

1. Patients taking metronidazole should avoid taking alcohol
2. The intrauterine contraceptive device (IUCD) is a possible risk factor for the development of PID. It is recommended that the IUCD be removed soon after antimicrobial therapy for PID is commenced. When an IUCD is removed contraceptive counselling is necessary.
3. Ciprofloxacin is contraindicated in pregnancy and not recommended in infections acquired in Asia.

**Conclusion**

Pelvic inflammatory disease is a serious complication of STIs. Women with PID usually present with lower abdominal pain. The symptoms of lower abdominal pain do not always indicate that the patient has PID and hence, other conditions should always be looked for and excluded. Lower abdominal pain also occurs in surgical and gynecologic conditions, and these conditions should be excluded by taking a history and by carrying out a careful

examination. It is best to refer all women with lower abdominal pain who give a history of any one or more of the following:

- Missed, overdue, or delayed period
- Recent abortion, delivery, or miscarriage
- Irregular and continuous vaginal bleeding

Also refer all women with lower abdominal pain in whom an examination reveals any one or more of the following:

- Abdominal guarding or rebound tenderness
- Abdominal mass
- Vaginal bleeding

**Summary**

The symptom of lower abdominal pain in women is extremely common and does not always indicate the presence of serious illness. However, women with certain serious conditions such as pelvic inflammatory disease (PID), acute appendicitis, ectopic pregnancy, and other complications of pregnancy may present initially with this symptom as well. Therefore, in managing women with lower abdominal pain care should be taken to exclude any serious condition before dismissing the symptoms of patient. PID is a condition in which there is infection in the female reproductive tract above the internal os of the cervix. This usually occurs as a result of an ascending cervical infection caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, anaerobic bacteria and other pyogenic bacteria. The immediate and long-term effects of PID include salpingitis, pelvic abscess, peritonitis, infertility, and predisposition to tubal ectopic pregnancy. Women with lower abdominal pain should be assessed carefully; if PID is the cause, they should be treated for gonococcal, chlamydial, and anaerobic bacterial infection. Other gynecological and surgical causes of lower abdominal pain and the immediate complications of PID require urgent referral to a specialist. PID is associated with significant morbidity and mortality.

## Introduction

Historically, Hippocrates first described that certain genital ulcers are accompanied by swellings in the groin, which were later termed as buboes.<sup>1</sup> Inguinal and femoral buboes are defined as the localized enlargement of the lymph nodes in the groin area that are painful and may or may not be fluctuant.<sup>2</sup>

## Etiology and Epidemiology

The most common causes of inguinal and/or femoral buboes are infection with *Haemophilus ducreyi*, the causative organism of chancroid, and *Chlamydia trachomatis*, L1-L3 strains, which cause lymphogranuloma venereum (LGV). A Thai study has shown that there is no role of other aerobic and anaerobic bacteria in the development of buboes associated with chancroid and LGV.<sup>3</sup> However, others have frequently isolated anaerobes from fluctuant chancroidal buboes.<sup>4,5</sup> Both chancroid and LGV are rare diseases even in tropical and subtropical regions. A recent review of sentinel surveillance of STIs in South Africa has shown that chancroid and LGV have declined considerably, which is attributed to implementation of syndromic management since 1994.<sup>6</sup> O'Farrell et al.<sup>7</sup> reported that among 162 patients with genital ulcers presented at an STI clinic in Durban between January and March 2004, 13.6% had LGV and 1.2% had chancroid. The cases were diagnosed by polymerase chain reaction (PCR). Data from an STD clinic in New Delhi, India, showed that during 1990–1993 chancroid constituted 21.3% of all genital ulcers in men, while during 2002–2004 only 6.9% of all men with genital ulcers had chancroid.<sup>8</sup> Corresponding figures for LGV for these periods were 5.7% and 0.4%, respectively.<sup>8</sup> In the 21 Century, it is still rarer to see the classical presentation of LGV with inguinal bubo. Since 2003 there has been a resurgence of LGV in western Europe, United States, and Australia in HIV positive MSM population; however, it is in the form of LGV proctitis rather than classical inguinal syndrome.<sup>9,10</sup> However, Sethi et al.<sup>11</sup> recently reported a series of classical inguinal syndrome from United Kingdom in HIV positive MSM population.

It is common to see inguinal suppuration as a complication of several other diseases. These include pyogenic infection of the leg, cat-scratch disease,<sup>12</sup> tuberculosis,<sup>13</sup> plague, and guinea worm infestation.<sup>14</sup> Secondary bacterial infection in the genital lesions of scabies and pediculosis pubis may result in tender inguinal lymphadenopathy (Fig. 58.1). Secondary bacterial infection in primary syphilitic chancre can also give rise to inguinal bubo (Fig. 58.2), which may suppurate if not treated. Atypical mycobacteria, like *Mycobacterium avium-intracellulare* and *Mycobacterium chelonae* have been reported to cause inguinal abscesses.<sup>15,16</sup> In many patients with inguinal bubo, no cause can be determined.<sup>3,17</sup> Some of these patients receive empirical antibiotic treatment before they report to the physician, making it difficult to isolate the pathogen. Nevertheless, a majority of such patients would respond to treatment regimens recommended for the management of inguinal buboes.<sup>3</sup>

## Clinical Features

About 50% of patients with chancroid develop buboes.<sup>18</sup> The buboes associated with chancroid are usually unilateral and are more prevalent in men than in women (Figs. 58.3

**Fig. 58.1:** Unilateral inguinal bubo associated with lesions of scabies on the glans and shaft of the penis.

**Fig. 58.2:** Inguinal bubo associated with secondary pyogenic infection in primary syphilitic chancre. All such cases should be managed with using genital ulcer algorithm.

**Fig. 58.3:** Unilateral, fluctuant inguinal swelling due to chancroidal bubo.

and 58.4). LGV associated buboes are usually unilateral, but may be bilateral in up to one-third of cases (Fig. 58.5).<sup>19</sup> The femoral lymph nodes are involved in approximately 20% of patients. A recent case series from United Kingdom reported unilateral or bilateral inguinal lymphadenopathy in 12 out of 13 MSM patients presented with LGV. In this series only 4 patients had concurrent genital ulcers and 1 patient had only genital ulcer without lymphadenopathy.<sup>11</sup>

Both chancroid and LGV associated inguinal buboes may be associated with constitutional symptoms including fever in about 27% of patients.<sup>3</sup> The inguinal swelling predominantly comprises of an enlarged lymph node; however, subcutaneous edema and abscess may also contribute to it.

As bubo enlarges, the pain increases and patient walks with a limp, bent at the waist in an attempt to limit the pain.<sup>20</sup> The pain sometimes is so severe that the patient may report to emergency department where the syndrome may be mistaken for an incarcerated inguinal hernia.<sup>15,21</sup> The bubo becomes fluctuant (Figs. 58.3 and 58.4) in about 1–2 weeks and, if

**Fig. 58.4:** Multiple ulcers of chancroid with unilateral inguinal bubo.

**Fig. 58.5:** Bilateral inguinal buboes of lymphogranuloma venereum. Note impending rupture. *Courtesy: Kamal Aggarwal, Sanjeev Gupta, and Vijay K Jain, Rohtak, India.*

not treated, aspirated, or drained, it ruptures on the surface to form a sinus or non-healing ulcer (Fig. 58.6). Concomitant genital ulcer is seen more frequently in patients with chancroid. Overall, genital ulcers are seen in about 40% of all patients who present with inguinal buboes. All such patients should be managed as per the guidelines for the management of genital ulcers.<sup>2</sup>

### Laboratory Investigations

A raised peripheral leukocyte count ( $>10,000/\mu\text{L}$ ) can be present. In all patients, pus should be aspirated for a laboratory workup. If buboes are not fluctuant, then a saline aspirate may provide the desired material. A Gram stain of aspirated pus may reveal *H. ducreyi*; however, it is not a sensitive method. Culture of the

**Fig. 58.6:** Ruptured inguinal bubo due to chancroid in a woman.

aspirated pus may grow *H. ducreyi* in patients with chancroid. However, the colonies are sparse and scattered even if a large amount of pus is inoculated.<sup>3</sup> The aspirated pus should be tested for *C. trachomatis* by immunofluorescence with a monoclonal antibody based assay. Electron microscopy may reveal elementary and reticulate bodies. Culture in McCoy cells may grow *C. trachomatis*, LGV strains.<sup>22</sup> Polymerase chain reaction remains the most sensitive method,<sup>22</sup> although not available at most of the centers where the syndrome is endemic. An ulcer workup (as described in Chapter 53) is recommended if a concomitant genital ulcer is present.

## Syndromic Management

The laboratory tests described above are mostly not available where the syndrome of inguinal buboes is most prevalent. Therefore, the World Health Organization (WHO) has recommended that all patients with inguinal and/or femoral buboes should receive treatment for chancroid and LGV, without laboratory confirmation of the diagnosis. The WHO algorithm for management of the syndrome of inguinal and/or femoral bubo(es) is shown in Fig. 58.7.

In most Asian countries, *H. ducreyi* is resistant to tetracyclines<sup>23</sup>; therefore, all patients with inguinal bubo should receive the following regime<sup>2</sup>: Ciprofloxacin, 500 mg orally, twice daily for 3 days and Doxycycline, 100 mg orally twice daily for 14 days or Erythromycin, 500 mg orally four times daily for 14 days. Some cases may require treatment longer than 14 days. Several isolates of *H. ducreyi* with intermediate resistance to either ciprofloxacin or erythromycin have been reported worldwide.<sup>24</sup> Azithromycin (1g orally) and ceftriaxone (250 mg intramuscular) offer the advantage of single-dose therapy for chancroid.

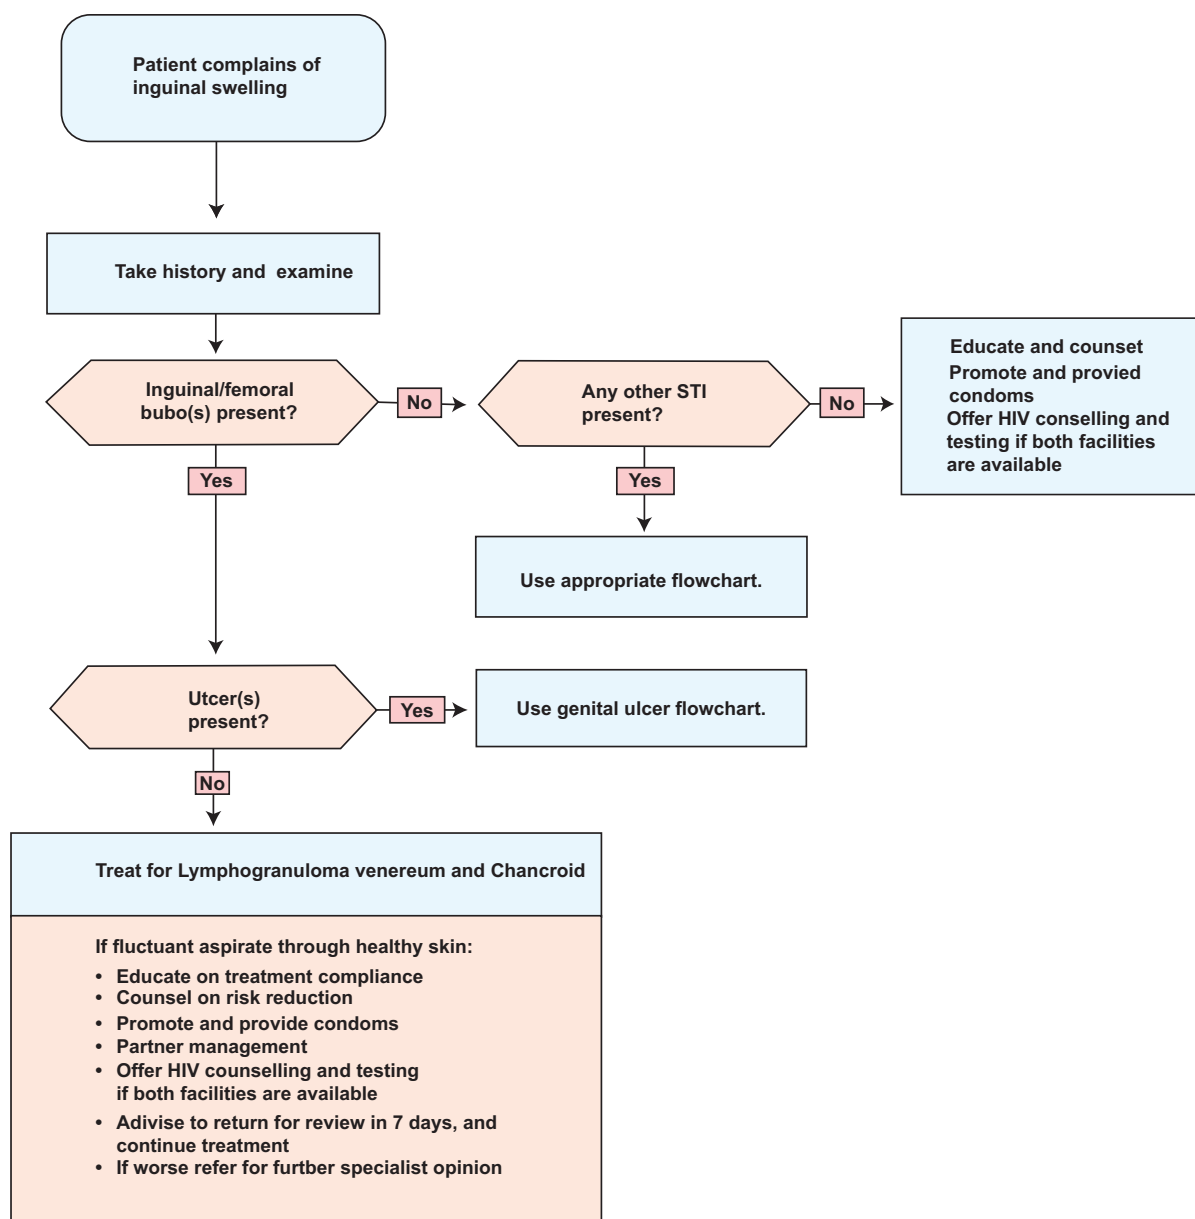

After initiation of therapy, patients usually improve symptomatically within 3 days and objectively within 7 days after therapy.<sup>24</sup> If no clinical improvement is evident at 1 week, the clinician must reconsider the diagnosis or rule out any coinfection with another STD or noncompliance and lastly resistant *H. ducreyi* strain<sup>24</sup> and the patient should be referred to a higher center for further management. Complete resolution of fluctuant buboes is slow.

The safety of azithromycin for pregnant and lactating women has not been established. Ciprofloxacin and doxycycline are contraindicated for pregnant and lactating women, children, and adolescents. So in such situations, erythromycin alone or in combination with ceftriaxone regimens should be used to treat inguinal bubo.

In patients coinfecting with HIV, there may be slower rate of healing or treatment failures. Recommended regimen is erythromycin base 500 mg orally four times a day for 21 days with or without ceftriaxone 250 mg intramuscular single dose. However, treatment failures have been frequently reported in HIV seropositive patients with chancroid from Africa for azithromycin,<sup>25</sup> ceftriaxone,<sup>26</sup> single-dose fleroxacin,<sup>27</sup> low-dose erythromycin or ciprofloxacin.<sup>28</sup> Such cases should be monitored closely.

## To Incise or not to Incise?

It is recommended that all fluctuant buboes should be aspirated with a 19 number needle through healthy skin to avoid rupture, which may result in sinus formation and delay in healing.<sup>2,17</sup> For this reason, most authors agree that incision and drainage or excision of nodes should be avoided.<sup>2</sup> However, in a study from the United States, Ernst et al.<sup>29</sup> compared incision and drainage and aspiration in fluctuant buboes of chancroid and concluded that the former may be preferable, as traditional needle aspiration requires frequent reaspirations. None of their patients developed discharging sinuses or nonhealing ulcers after incision and drainage. On the other hand, Lewis<sup>18</sup> opined that incision and drainage cannot be recommended in the tropics (where the “syndrome” is more prevalent) as it may be associated with increased postoperative morbidity.

**Fig. 58.7:** WHO algorithm for the management of inguinal buboes. *Courtesy:* WHO guidelines for the management of sexually transmitted infections. WHO/HIV/2003.09.

### Summary

- The syndrome of inguinal and femoral buboes is defined as the localized enlargement of the lymph nodes in the groin area that are painful, and may or may not be fluctuant.
- The most common causes of inguinal and/or femoral buboes are infection with *Haemophilus ducreyi*, the causative organism of chancroid, and *Chlamydia trachomatis*, L1-L3 strains, which cause lymphogranuloma venereum.
- Both chancroid and LGV are rare diseases even in tropical and subtropical regions; however, there has been a resurgence of LGV in Western Europe, United States and Australia in HIV positive MSM population, although the majority of them does not present with the classical inguinal syndrome. On the other hand it is common to see

inguinal suppuration as a complication of several other diseases, such as pyogenic infection of the leg, cat-scratch disease, tuberculosis, plague, guinea worm infestation and secondary pyogenic infections of genital ulcers due to other STD pathogens.

- Syndromic management of patients with inguinal bubo comprises of Ciprofloxacin, 500 mg orally, twice daily for 3 days and Doxycycline, 100 mg orally twice daily for 14 days, or Erythromycin, 500 mg orally four times daily for 14 days. In regions where Quinolone-resistant strains of *H. ducreyi* are reported, Azithromycin, 1g orally or Ceftriaxone 250 mg intramuscular are good single-dose alternatives.
- If patient has concomitant genital ulcer, they should be managed as per the guidelines for the management of genital ulcers.

"This page intentionally left blank"

## Introduction

Balanitis is an acute or chronic inflammation of the glans penis. Posthitis refers to an inflammation of the mucosal surface of the prepuce. The term balanoposthitis thus refers to an inflammation of the glans and penile mucosa. Balanitis is a common condition in male patients attending sexually transmitted diseases (STDs)/genitourinary medicine (GUM) clinics. There is scarcity of data on epidemiology of balanitis. The frequency of balanitis is reported to be 10.7% in Portugal and 11% in UK among men attending STD/GUM clinics with little information from other parts of world.<sup>1,2</sup> It can be a transient, recurrent, or persistent problem. Nevertheless, despite its frequency, this condition often receives scant attention.

Balanitis is more common among uncircumcised men, possibly as a result of poorer hygiene and aeration or because of irritation by smegma. Underlying medical conditions like diabetes mellitus can also predispose to balanitis, which may be more severe. Pre-malignant lesions of the balanopreputial area, although not frequent, represent a difficult diagnosis and therapeutic challenge.

The disease starts as inflammation with or without break in the continuity of the surface of glans or prepuce. This is followed by edema of the prepuce, phimosis, thin whitish or thick malodorous subpreputial discharge (minimal to copious) accompanied by pain, pruritus, and occasionally burning during micturition. Balanitis covers a variety of unrelated conditions with similar clinical presentation. It results from infective, irritative, allergic, traumatic, and inflammatory causes and pre-malignant lesions have also been identified (Table 59.1).<sup>3,4</sup> *Candida* species are considered to be the commonest cause of infective balanitis, most being sexually acquired.<sup>3-6</sup> The manifestations of balanoposthitis, irrespective of etiology, are much more severe in the presence of HIV infection, particularly in the advanced stages.<sup>7</sup> In this chapter, only the common and important conditions causing balanitis/balanoposthitis have been discussed.

## Balanitis in Children

Balanoposthitis in children is a rare entity. If present, it is usually seen in the age between 2 and 5 years and is primarily due to group

A  $\beta$ -hemolytic streptococci, where the mode of transmission appears to be autoinoculation from other sites.<sup>3</sup> It is often caused by mixed infection, which includes *Escherichia coli*, *Pseudomonas*, *Klebsiella spp.*, *Serratia spp.*, and *Streptococcus spp.* Such children present with an erythematous moist balanoposthitis secondary to a non-retractile prepuce.

## Balanitis/Balanoposthitis in Adults

### ETIOLOGY

The causes can be broadly classified under two groups—infections and dermatological diseases (Table 59.1).

### Infections

There are a wide variety of causes for balanitis, but infection is

**Table 59.1:** Etiology of Balanitis/Balanoposthitis

#### Infections

**Mycotic:** *Candida*, Dermatophytes, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, *Penicillium marneffei*

- **Bacterial:** *Streptococci*, *Staphylococcus aureus*, *Bacteroides spp.* and other Anaerobic bacteria, *Mycobacterium tuberculosis*, *Treponema pallidum*, *Haemophilus ducreyi*, *Mycoplasma*, *Neisseria gonorrhoeae*, *Gardnerella vaginalis*
- **Viral:** *Herpes simplex virus*, *Human papillomavirus*, *Herpes zoster virus*
- **Protozoan:** *Trichomonas vaginalis*, *Entamoeba histolytica*, *Leishmania*
- **Parasitic:** Scabies (*Sarcoptes scabiei* var *humanus*), cutaneous larva migrans (*Ancylostoma braziliense* etc.)

#### Dermatological diseases

- Allergic & irritants contact dermatitis
- Dermatoses (see Table 59.2)
- Premalignant conditions—Bowen disease, erythroplasia of Queyrat
- Malignancy—squamous cell carcinoma, basal cell carcinoma, metastasis.

#### Adverse drug reactions

Sulfonamides, analgesics, anticonvulsants, chemotherapeutic agents, foscarnet, warfarin

#### Miscellaneous

Trauma, viz. zip fastening, due to beads, piercing of the frenulum, etc.

the most common reported etiology. In a study from Sweden consisting of 100 patients with balanoposthitis, there was a significantly higher frequency of positive cultures than in the control group (59% and 35%, respectively;  $p < 0.05$ ). *Staphylococcus aureus* was found in 19%, group B streptococci in 9%, *Candida albicans* in 18%, and *Malassezia* in 23% of patients. In the control group, *S. aureus* was not found at all, whereas *C. albicans* was found in 7.7%, and *Malassezia* in 23% of men.<sup>8</sup>

Among 219 men with balanitis attending the STD Clinic of Hospital de S. João, a university hospital in Porto, Portugal, between 1995 and 2004, 118 (53.9%) had clinically been assumed to suffer from infective balanitis. In 75 (63.6%) patients, the diagnosis was confirmed by culture studies. *C. albicans* was isolated from 24 (32%) patients. *Staphylococcus spp.* and groups B and D streptococci were the most frequently isolated bacteria.<sup>2</sup>

### Mycotic Infections

**Candidal Balanoposthitis** This is considered to be the most common cause and is usually due to infection with *C. albicans*. First described by Engman in 1920, candidal balanoposthitis is a well-recognized condition responsible for up to 35% of all cases of infectious balanitis.<sup>2,5</sup> There is little information about candida colonization and infection in men.<sup>9</sup> According to several studies, less than 20% of unselected males may carry yeasts on the penis.<sup>10,11</sup> Reported predisposing factors for male genital candidosis include diabetes mellitus, immunosuppression, uncircumcised state, having a sexual partner with vulvovaginal candidiasis or a recent use of antibiotics.<sup>2,3,12,13</sup>

In a study of 478 men attending a STD clinic in Portugal, the prevalence of candida colonization was 26.2% and of candidal balanitis was 18%. At age above 40 years, diabetes mellitus and more than 10 candida colonies recovered by culture were risk factors for candida balanitis. Surprisingly, no significant association was noted between uncircumcised men and candida infection in this study.<sup>14</sup>

Although carriage of yeasts on the penis is not uncommon, only a few get the symptomatic disease. Candida balanitis is more prevalent in men having sexual partners with vulvovaginal candidiasis.<sup>15</sup> It is generally acquired sexually and is often self-limiting. The clinical features of candida balanitis include mild-glazed erythema and papules with or without satellite pustules on the glans penis. These break to leave behind superficial erosions with a collarette of whitish scales with moist and curdy accumulation under the prepuce. These infections can spread to involve the scrotum and the groins. In circumcised patients, there may be a red glazed appearance of the glans with a slightly scaly edge. Usually, patients complain of local burning and pruritus; however, this clinical aspect is often non-specific.<sup>2</sup> In men with diabetes mellitus or in immunocompromised hosts, an acute fulminating edematous or ulcerative variant may occur.<sup>16</sup> Diabetic candidal balanitis occurs not infrequently in older males, often with a fissured and slightly indurated prepuce that is difficult to retract. In a study of infective balanitis, 76.9% of patients with microbiologically

confirmed candida balanitis had diabetes mellitus.<sup>2</sup> There are often symptoms of vague ill health rather than classical symptoms of the onset of diabetes mellitus in younger persons.<sup>17</sup> Occasionally, a patient develops a hypersensitivity reaction to yeast infection in the partner. This presents with burning and redness, which occurs a few hours after intercourse, but is actually without infection on microscopy and/or culture.<sup>16,18</sup>

In practice, candida balanitis is often a clinical diagnosis without systematic laboratory confirmation; however, some investigators have stressed the relevance of the isolation of yeasts for the definitive proof of a fungal infection.<sup>14</sup> On microscopy, pseudohyphae can be easily identified in KOH, saline, or Gram stained preparation. It is known that the sampling method for culture has a strong influence on the percentage of isolates. The quantity of material collected is often small and it certainly contributes to the incidence of negative cultures. In clinically suspected cases of candidal balanitis, culture negativity of up to 36% has been reported.<sup>2</sup> Adhesive tape method has been proven to be more accurate than swabbing. Improved diagnostic procedures, with higher sensitivity and specificity, are mandatory in order to rule out an over-diagnosis of candida balanitis. Serum glucose levels and urine analysis to exclude diabetes mellitus are usually recommended in men with candida balanitis.<sup>19</sup> Candidal balanitis is often commonly confused with irritant balanitis, circinate balanitis, contact allergy, or plasma cell balanitis of Zoon.

**Treatment:** Diagnosis based solely on clinical grounds is often inadequate. Some patients are often assumed to suffer from candida balanitis without laboratory confirmation. Underlying disorders causing the infection should be addressed. Subpreputial normal saline washes twice daily are an essential prerequisite. Once the condition has subsided, daily washing under the foreskin is to be maintained as a regular habit. It is important to emphasise that both partners should be treated at the same time. There could be recurrent episodes of infection.

Treatment options usually involve topical or oral azole agents. Clotrimazole, miconazole, and econazole are the topical antifungal agents usually recommended. Topical azoles applied twice daily have been shown to have a cure rate of more than 90%. Oral treatment with fluconazole (150 mg as a single dose) is recommended when symptoms are severe, in recalcitrant cases, or with concomitant diabetes. A single dose of fluconazole, 150 mg orally, has been shown to be effective in up to 100% of the cases.<sup>20</sup> In case of presence of candidal hypersensitivity, a combination of a mild topical corticosteroid and an antifungal may be more effective.

**Dermatophytes** *Trichophyton rubrum* and *T. mentagrophytes* are rare causes of balanoposthitis. Six cases have been reported from Japan.<sup>21</sup> In a report of nine cases from Italy, the lesions, situated on the penis, glans, and scrotum, were preceded by dermatophytosis in other sites (groins: five cases; feet: two cases; toenails: 2 cases; hands in one; and beard in another). Mycological examination consisting of direct microscopy and culture led to isolation of *Trichophyton rubrum* in five cases,

*Epidermophyton floccosum* in two, and *T. mentagrophytes* var. *interdigitalis* in the others. Clinical diagnosis is not always easy. In three cases the lesions had been misdiagnosed as eczema.<sup>22</sup> A 27-year-old Japanese male student with tinea of the glans penis having lesions as crop of papules has been described.<sup>23</sup> Topical antifungals normally suffice, oral antifungals like griseofulvin or fluconazole may be more effective.

**Pityriasis Versicolor** Glans penis involvement is generally reported in association with extensive skin involvement. The causative organism is *Malassezia furfur* and diagnosis can be confirmed on KOH examination or culture. Despite the common occurrence of pityriasis versicolor of the skin, involvement of glans penis is rarely noted with only few cases in literature indicating that this might be missed, undiagnosed, or diagnosed as other condition. They present clinically as discrete, circinate, finely scaly, hypopigmented areas on the glans, which fluoresce yellow under Wood's light. The lesions can be treated with topical azoles.<sup>24</sup>

**Deep Fungal Infections** Disseminated *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, and *Penicillium marneffei* can cause balanitis. *Histoplasma* balanitis manifests as punched out ulcers, which are non-tender and have an indurated margin. *Cryptococcus neoformans* produces a necrotizing balanitis in HIV positive individuals. *P. marneffei* can cause ulcerative balanitis in HIV positive men. The infections respond to surgical debridement, intravenous amphotericin B and, oral ketoconazole.<sup>25</sup>

### Bacterial Infections

Bacteria represent the second most common cause of infectious balanitis, *Streptococcus* spp. being most frequently incriminated. The pathogenic nature of some bacterial isolates from glans penis remains controversial. Their presence does not necessarily mean that they are the cause of balanitis, as such organisms are common members of the indigenous mucosal microbial population.<sup>16</sup> Some authors have reported that bacteria, such as *Staphylococcus epidermidis*, *Klebsiella*, *Enterococcus*, and *Escherichia coli* may cause mild balanoposthitis.<sup>26</sup>

**Syphilitic Balanitis of Follman** It is rare. It appears in the later stages of primary syphilis or early in secondary syphilis (Figs. 59.1 and 59.2). It presents as multiple circinate lesions, which erode to cause irregular ulcers, or as a swollen glans covered with partially coalescent white flat papules and plaques.<sup>3</sup> Rarely, this form of balanitis may present with multilocular pustules.<sup>16</sup> Spirochaetes can be demonstrated from the lesions through dark-field examination. It is possible that cases of Syphilitic balanitis of Follman are in reality much more frequent than is generally recognized; when treponemes are found in a primary chancre in the region of the glans or prepuce, we do not normally look further for them in the frequently accompanying inflamed glans penis.<sup>27</sup> Patient should be managed as per CDC/WHO recommendations for the stage of syphilis. Benzathine penicillin 2.4 million units as a single intramuscular injection (half in each buttock, after a test dose) is effective.<sup>28</sup>

Fig. 59.1: Primary syphilis ulcer on glans penis.

Fig. 59.2: Secondary syphilis rash involving penis.

**Chancroid** The glans penis and prepuce are nearly always affected in the disease caused by *Haemophilus ducreyi*. The typical clinical presentation is painful shallow ulcers with ragged and undermined edge, granulomatous base, and purulent exudate. Complications include phimosis in men, phagedenic ulceration due to secondary bacterial infection and typically a posthitis is found with preputial fissuring. Treatment is with adequate doses of erythromycin, ceftriaxone, azithromycin, or ciprofloxacin.<sup>28,29</sup>

**Chlamydial Balanitis** *Chlamydia trachomatis*, specifically D to K serotypes, is responsible for a large number of genital infections like non-specific urethritis, epididymitis and epididymo-orchitis, but little is known about the epidemiology of local complications in men. Balanitis arising in a patient with non-gonococcal urethritis (NGU) or proctitis should raise suspicion of this condition.<sup>16</sup> Tetracyclines or other drugs recommended for chlamydial infection should be given in adequate doses.<sup>25</sup>

**Mycoplasma Balanitis** It is observed in about 10% of patients with NGU caused by mycoplasmas. Clinically, it presents as simple erythema or circinate lesions, which have a tendency to hemorrhage. Mycoplasmal balanitis may also occur with no evidence of concurrent dysuria.<sup>16</sup> Detection of *M. genitalium* in men with acute NGU is associated significantly with balanitis and/or posthitis. The association is biologically plausible and may have a role in HIV-1 transmission and susceptibility.<sup>30</sup> It should be treated with systemic tetracyclines.

**Gonococcal Balanoposthitis** Infection of penile skin and subpreputial mucosa by *Neisseria gonorrhoeae* is less common. Gonococcal balanoposthitis can be a primary manifestation of this infection. It presents as tender ulcers, pustules, or furuncles on the prepuce or shaft of the penis. Abscesses of the prepuce and progressive ulceration of the glans with lymphadenopathy may also be seen. The incubation period is 2 to 10 days and trauma is not a prerequisite. These infections may occur in the absence of urethral symptoms although urethral swabs obtained from 4 of 6 patients, in a study, were positive for *N. gonorrhoeae*.<sup>16</sup> Recurrent gonococcal balanoposthitis may result in secondary hypopigmentation of the glans. The infection is confirmed by Gram stain of pus demonstrating intracellular gram-negative diplococci, and also by culture. Recommended treatment includes a single dose of ceftriaxone, cefixime, or ciprofloxacin. Recently, quinolone resistant strains have become prevalent in many Asian countries. Simultaneous treatment with doxycycline or azithromycin for *C. trachomatis* is also advocated.<sup>28</sup>

**Gardnerella Vaginalis** It has been isolated in 31% of the patients with non-candidal balanoposthitis and up to 75% of these cases have a concomitant infection with anaerobic pathogens (*Bacteroides* spp.).<sup>31</sup> It is likely to be sexually acquired, as evidenced by high isolation rates from urethra or urine in partners of women with *Gardnerella vaginalis* vaginitis. The symptoms of pure *Gardnerella* infection are milder than those in combination with anaerobic infection. The clinical features include irritation of the prepuce and the glans penis, macular erythema, and a subpreputial discharge with fishy odor. Treatment is with metronidazole along with good local hygiene.

**Group B Streptococci** These are usually carried asymptotically in the adult genital tract but may sometimes be associated with balanitis. Rate of carriage on the glans in heterosexuals and homosexuals varies between 16.6% and 39.3%, respectively,<sup>16</sup> although no balanitis has been reported from the latter group. The role of sexual transmission though was unclear earlier,<sup>32</sup> it is now considered to be sexually transmitted.<sup>33</sup> Clinically, streptococcal balanitis presents as a non-specific erythema, with or without discharge. More rarely, if abrasions are present, streptococci may invade deeper tissue to produce penile cellulitis.<sup>34</sup> Group A  $\beta$ -hemolytic streptococci have also been reported as a cause of balanitis, more commonly in uncircumcised children. They present with erythematous moist balanitis, where the mode of transmission is autoinoculation.<sup>35</sup> Following fellatio, pyoderma caused by group A  $\beta$ -hemolytic streptococci has been reported. In a study of 189 adult patients with balanoposthitis, *Streptococcus pyogenes* was isolated in 47 cases with route of infection considered to be predominantly sexual.<sup>36</sup> Penicillins and cephalosporins are effective in the treatment.

**Staphylococcus Aureus** This organism is an infrequent cause of balanitis. Although carriage is not associated with symptoms, toxic shock syndrome occurring after a *Staphylococcus aureus* balanitis has been documented in a 5-year-old boy.<sup>37</sup>

**Anaerobic Bacterial Infection** Erosive and gangrenous balanitis resulting from a symbiotic infection of anaerobes and non-treponemal spirochaetes account for 8–30% of all cases of ulcerative balanoposthitis.<sup>38,39</sup> *Bacteroides* spp. are the most common isolates from these mixed infections. Cree et al.<sup>40</sup> proposed the term anaerobic erosive balanitis for this condition.

The microorganisms that cause anaerobic balanitis may be transmitted from mouth by fingers contaminated with saliva or more commonly orogenital contact.

All reports of anaerobic erosive balanitis have been in uncircumcised males. Predisposing factors include relative phimosis and poor local hygiene. Patients initially have extensive tender erosions of the glans accompanied by foul-smelling discharge. Edema of the prepuce causing phimosis is not uncommon. Diagnosis is confirmed by gram staining, dark-field examination, and culture. Transmission is thought to occur most commonly by orogenital contact. The response to treatment with metronidazole is rapid, whereas neglected cases may progress to phagedenic complications.

Necrotizing fasciitis of the male genitalia originally described by Fournier, is rare. Paraphimosis, penile erosions, local trauma, circumcision, and periurethral abscesses have been associated with necrotizing fasciitis of the penis. Clinically, the infection begins as an area of cellulitis which may progress to a blue-brown ecchymotic discoloration.<sup>16</sup> The lesion is extremely painful. Mixed population of gram negative bacilli and anaerobes, especially *Bacteriodes* spp. are isolated most commonly. Diabetes mellitus seems to be a predisposing factor. Broad-spectrum antibiotics are required. Sometimes surgical debridement may be necessary.

### Viral Infections

**Herpes Simplex Virus** Primary genital herpes is classically characterized by multiple grouped vesicles in bilateral distribution, moderate-to-severe local pain and dysuria, with tender inguinal lymphadenopathy, and systemic symptoms. Rarely, primary herpes can cause a necrotizing balanitis presenting with a necrotic black eschar on the glans accompanied by vesicles elsewhere. This may be associated with headache, dysuria, fever, and inguinal pain.<sup>41–43</sup>

Recurrent and persistent ulcerative herpes simplex virus lesions are among the most common infections amongst the patients with HIV/AIDS. Extremely painful, persistent, large, and necrotizing ulcerated areas involving the prepuce, glans, shaft of the penis, and pubic region in males can occur in HIV seropositive individuals with advanced disease.

Treatment is with acyclovir, which requires a prolonged course in the HIV infected.

**Human Papillomavirus** Majority of the anogenital warts are caused by human papillomavirus (HPV) infection. It is one of the most common sexually transmitted disease with a rising incidence. HPV produces the classical warty lesions on any part of the male genitalia, commonly known as condyloma acuminata. Although very uncommon, a verrucous carcinoma that is locally aggressive but rarely metastatic, the Buschke–Löwenstein tumor

**Fig. 59.3:** Buschke–Löwenstein tumor (giant genital wart).

**Fig. 59.4:** HPV balanitis (pseudoeplitheliomatous keratotic and micaceous balanitis).

(Fig. 59.3) may be seen. Rarely a picture with hypertrophic and hyperkeratotic plaque lesions (PEKB) on the glans may occur (Fig. 59.4). HPV may be associated with a chronic balanitis presenting as patchy maculopapules or erythematous macules on the inner aspect of prepuce and glans (Fig. 59.4).<sup>44</sup> This becomes acetowhite after application of 5% acetic acid. It is a non-specific test, as other inflammatory lesions may also provoke similar changes on acetic acid application. In one study up to 44% of men with HPV balanoposthitis had macular lesions. Symptoms included redness, itching, burning, tenderness, and fissuring of the glans.<sup>45</sup> Lowhagen et al.<sup>46</sup> demonstrated high-risk HPV types (6, 18, 31, and 33) in 56% macular lesions. Uncircumcised men are more susceptible to this condition.<sup>16</sup> In atypical cases of balanoposthitis, HPV etiology should also be considered. Treatment is with podophyllotoxin, imiquimod or topical 5-fluorouracil, all of which have been found to be effective. Bowenoid papulosis appear as 2-to-3 mm papules, often multiple on external genitalia including glans penis (Fig. 59.5). Histologically there is cellular atypia resembling Bowen disease or squamous cell carcinoma *in situ*. These lesions are usually infected with HPV-16, which suggests that bowenoid papulosis may represent a precursor of penile cancer.

**Fig. 59.5:** Bowenoid papulosis.

### Protozoal Infections

**Trichomonas Vaginalis** Although *T. vaginalis* infection is regarded primarily as a disease of women, it also occurs in men. About 15–50% men with trichomonal infection remain asymptomatic carriers. In symptomatic men, common complaints include scanty, clear to mucopurulent discharge, dysuria, and mild pruritus or burning sensation immediately after sexual intercourse. Other symptoms include urethral irritation and frequency. Rarely the patient may complain of copious purulent urethral discharge, or complications such as prostatitis and epididymitis. *T. vaginalis* infection may present as an erosive balanitis, which may lead to phimosis.<sup>16</sup> A long prepuce has been noted as a predisposing factor. A wet mount from the subpreputial sac may demonstrate the organism. The condition responds well to metronidazole.<sup>47</sup>

**Amoebic Balanitis** First reported by Straub in 1924, it is caused by a protozoan *Entamoeba histolytica*. Two modes of transmission are recognized; autoinoculation from amoebic dysentery and vaginal or anal intercourse with an infected person. This severe form of balanitis is marked by edema with phimosis, pain, dysuria, and ulceration of the glans penis. Clinically, the lesions may suggest an ulcerative carcinoma, but the major distinguishing feature is the presence of pain. The diagnosis in men was made by biopsy, culture, smear, or wet preparation. Genital amoebiasis lesions generally respond swiftly to a standard course of metronidazole treatment (800 mg three times daily for 5 days). Circumcision may be required in some cases.<sup>7,48</sup>

### Parasitic Infection

**Scabies** It is an infestation with a mite, *Sarcoptes scabiei var hominis*. Primary lesions in scabies are burrows, papules, vesicles, and small nodules. Burrows are the pathognomonic lesions and are 5–15 mm long linear eruptions most frequently found in the web spaces of the fingers, sides of the hands, and flexor surfaces of the wrist. More common than the burrows are the erythematous papules, which are more extensively distributed. The chief clinical symptom is pruritus, which is usually worse at night. Sometimes scabietic lesions are seen predominantly over the

**Fig. 59.6:** Scabies with genital involvement.

genitalia (Fig. 59.6) in adult males which may indicate a sexual transmission. They are raised, slightly elongated, nodular lesions with the burrow tracks each seen as a thin, black, and irregular line. Mechanical scratching by the patients removes the roof of the burrow leaving a shallow longitudinal ulcer. The lesions are commonly seen on the preputial skin, shaft of penis, scrotum, and glans penis. The preferred treatment for scabies is permethrin 5% cream applied from neck to the feet, with particular attention given to the perianal and genital areas, and to the free nail edge and folds; the cream is rinsed off after 8–14 hours. All household members of the scabietic patient, and any sexual partners, should be treated concomitantly.<sup>16</sup>

## Dermatological Diseases

### Allergic and Irritant Contact Dermatitis

Allergic contact dermatitis of the genital area may result from condoms, lubricants, feminine hygiene deodorant spray, cauterizing agents, habit of applying strong antiseptics to avoid getting STDs after sexual exposure, and use of spermicides. Involvement of the adjacent area may give the clue to the underlying etiology. More often, contact dermatitis is irritant, resulting from persistent moisture and maceration. Clinically, genital allergic contact dermatitis is characterized by erythema, edema, and exudation (Fig. 59.7).<sup>16</sup> Acute contact dermatitis of the penis is

**Fig. 59.7:** Allergic contact dermatitis leading to paraphimosis.

usually associated with marked edema because the skin covering the genitalia is thin and elastic. Men using latex contraceptive products may present with edematous, weeping eruption of acute contact dermatitis.<sup>49</sup> Rarely, immediate hypersensitivity reaction may be life-threatening.

Irritant contact dermatitis results from non-immunological physical or chemical damage to the skin. The eruption primarily occurs in the area of contact with irritants, and may develop from the use of certain soaps, detergents, or topical medications. In the acute phase, the lesions are erythematous, oozy, and crusted, whereas with recurrent or prolonged exposure to irritants, the skin becomes lichenified and hyperkeratotic. There is a wide spectrum of clinical manifestations varying from mild balanitis to edema of the whole penis extending to the groins.

Mild cases can be treated with low potency corticosteroid creams. Severe cases of allergic contact dermatitis may require treatment with systemic corticosteroids. The identification of the contact allergen depends on history and usually requires “patch” testing. This procedure is especially indicated for cases in which inflammation persists despite avoiding the suspected allergens and after appropriate topical therapy. Management will depend on the severity of the reaction and avoidance of the precipitant is required.<sup>50</sup> Topical treatment with emollients/moisturizers in addition to specific therapy is helpful in majority of these patients.

### Dermatoses Causing Balanitis

Many dermatological conditions may also have a predilection for the male genitalia (Table 59.2). Psoriasis, lichen planus, and seborrheic dermatitis are common and evidence of involvement at other sites should be sought. In many cases, male genital

**Table 59.2:** Dermatoses Causing Balanitis/Balanoposthitis

- Psoriasis
- Lichen planus/nitidus
- Fixed drug eruptions
- Erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis
- Seborrheic dermatitis
- Pityriasis rosea
- Crohn disease
- Ulcerative colitis
- Autoimmune blistering disorders—Pemphigus, bullous pemphigoid, cicatricial pemphigoid, linear IgA disease, epidermolysis bullosa acquisita
- Lichen sclerosis (balanitis xerotica obliterans)
- Plasma cell balanitis (Zoon balanitis)
- Necrobiosis lipoidica
- Hypereosinophilic syndrome
- Reiter syndrome (balanitis circinata)
- Xanthomatosis
- Histiocytosis
- Sarcoidosis
- Porokeratosis
- Leprosy
- Aphthous ulcer (Behcet disease)
- Pyoderma gangrenosum

**Fig. 59.8:** Psoriasis involving glans penis.

**Fig. 59.9:** Lichen planus involving glans penis.

involvement with psoriasis is part of a more generalized cutaneous disorder. The typical psoriatic scale is usually not apparent because of moisture and maceration (Fig. 59.8). Lichen planus presents with violaceous flat-topped papules and frequently annular lesions on the glans and shaft of the penis (Fig. 59.9). Balanitis may occur both with Crohn disease and ulcerative colitis involving the perianal and genital areas. Dermatitis artefacta of the genitals has also been reported.

### Lichen Sclerosus

Lichen sclerosus (LS) of the male genitalia is a chronic inflammatory disorder presenting as a chronic, sclerosing atrophic process of the glans and foreskin, leading to meatal stenosis and acquired phimosis. Most authors consider LS of the penis synonymous with balanitis xerotica obliterans.<sup>51,52</sup> It can remain completely asymptomatic for some time however, the main symptoms are pain, irritation, disturbance of sexual function, and urinary symptoms including obstruction. The initial lesions of LS are white, polygonal, and flat-topped papules or plaques. The lesions progress to ivory colored atrophic and sclerotic white plaques. Rarely, this can present as a recurrent bullous balanitis, with the development of painful blisters and ulceration that may be precipitated by local trauma. The clinical appearance is of porcelain white plaques on the glans, often with involvement of the prepuce, which becomes thickened, and non-retractile and fissures develop on attempted retraction. In active disease,

hemorrhagic vesicles may be seen. The changes affect squamous skin, leaving atrophic areas that cause cicatricial shrinkage leading to urethral stenosis and phimosis.<sup>50–52</sup>

The condition may affect any age group, but is most common in middle-aged uncircumcised men. The incidence of genital LS in young boys with phimosis has been estimated to be about 15%, and circumcision specimens from children with phimosis often show the characteristic histological changes.<sup>53</sup> In a prospective study of 43 men with narrowing of the prepuce referred for circumcision, LS was present in 32%. Of these only 21% of the men had been clinically diagnosed as having LS.<sup>54</sup> Histology initially shows a thickened epidermis, followed by atrophy and follicular hyperkeratosis, basal cell degeneration, upper dermal edema, homogenization of collagen, and a chronic inflammatory infiltrate. The course is chronic and relapsing, and although it may sometimes arrest, but the areas of atrophy do not regress.

The association between LS and squamous cell carcinoma (SCC) is a well-known phenomenon in women, and it has been observed in 3–6% of patients with vulvar involvement. There are reports of men developing penile SCC in association with LS.<sup>50</sup> In a retrospective study of 86 uncircumcised patients with LS, five (6%) developed malignant changes.<sup>55</sup> Three patients had SCC, one had carcinoma *in situ* and one had verrucous carcinoma. The presence of HPV 16 was shown by PCR in four of the five cases. In a study of 20 patients with penile SCC, half had histological evidence of LS.<sup>56</sup> Periodic follow-up of patients with LS is advisable, including biopsy of any clinically suspicious lesion.

Biopsy is not essential in all cases and is indicated in atypical cases to differentiate from penile cancer. Early diagnosis and treatment of LS are very important in preventing the urological complications of the diseases such as urethral stricture. Treatment of LS depends on the anatomic location of the lesions and their extent and severity, together with the rapidity of progression of the disease process. Short courses of potent topical corticosteroids form the mainstay of treatment.<sup>51–53</sup> Topical pharmacotherapy is useful in the early stages to reduce the initial symptoms and slow down the progression, but is not effective in all cases and is not curative. Meatal stenosis, phimosis, scar adhesions, fissures, erosions of glans and prepuce, and involvement of the urethra are indications for surgical treatment.<sup>51,52</sup>

Recently topical calcineurin inhibitors (tacrolimus, pimecrolimus) have been found to be effective in patients not responding to corticosteroid treatment and as maintenance or combination therapy with topical corticosteroids.<sup>57,58</sup> However, concerns remain with regard to their malignant potential with long-term use. As LS is a potentially precancerous dermatosis, topical calcineurin inhibitors should be used with caution in this disorder.<sup>57</sup> In a placebo-controlled randomized trial, acitretin was found to be safe and effective for the management of severe, long-standing LS of the male genitalia.<sup>59</sup> Other therapies tried in LS are topical calcipotriol, photodynamic therapy, and laser ablation. Testosterone ointment has also been advocated.<sup>60</sup>

### Plasma Cell Balanitis (PCB)

PCB or balanitis circumspecta plasmacellularis is a benign, idiopathic condition first recognized by Zoon in 1952. PCB typically presents as a solitary, smooth, shiny, red-orange plaque on the glans and/or the prepuce of an uncircumcised, middle-aged to older man. The lesion often exhibits pinpoint purpuric cayenne pepper surface spotting with an area of yellow hue. Vegetative, erosive variants, and multiple lesions have been reported.<sup>16</sup> Lesions analogous to PCB have been reported on the vulva, nose, lips, oral cavity, epiglottis, and larynx. PCB tends to be chronic and is often present for months to years before the patient reports for consultation. Symptoms are minimal, but may include mild tenderness pruritus and subpreputial discharge.

Diagnosis is confirmed by the distinctive histological findings of epidermal atrophy with complete effacement of the rete ridges. Diamond shaped “lozenge keratinocytes” are common with uniform intercellular spaces termed “watery spongiosis.” A dense lichenoid subepidermal infiltrate composed largely of plasma cells is characteristic. Erythrocyte extravasation, hemosiderin deposition and epidermal ulceration are often noted.<sup>61</sup> All confirmed cases have involved uncircumcised men. The etiology and pathogenesis of PCB is speculative; heat, friction, poor hygiene, chronic infection with *Mycobacterium smegmatis*, trauma, response to an unknown exogenous agent, immediate hypersensitivity response to IgE class antibodies, and hypospadias have been implicated as predisposing factors. The treatment of choice for PCB is circumcision.<sup>62</sup>

Temporary relief is usually achieved by topical corticosteroids, with or without topical antibiotics or antifungals, but these are generally not curative. Resistant cases can be treated with the carbon dioxide laser or erbium-YAG laser ablation.<sup>63</sup> Recently, topical calcineurin inhibitors (tacrolimus, pimecrolimus) have been used as second-line treatment agents with limited success in patients with refractory lesions or in those not opting for circumcision.<sup>64–66</sup>

The distinction of this lesion from similar lesions is rather important, and a large group of disorders such as premalignant, infective, and other inflammatory penile diseases should be definitely taken into consideration in the differential diagnosis. It seems that circumcision might be the current “gold standard” for treatment of this disorder.<sup>67,68</sup>

### Circinate Balanitis

Balanitis circinata is a rather classic mucocutaneous manifestation of Reiter syndrome, a multisystem disease that is clinically characterized by the triad of nongonococcal urethritis, arthritis, and conjunctivitis. Balanitis circinata has been reported in 12–70% of men with Reiter disease. Circinate balanitis manifests as a well-demarcated, moist, erythematous plaque with a ragged or scalloped white border on the glans penis (Fig. 59.10). In circumcised patients, the lesions are dry and hyperkeratotic, and may appear as psoriasiform plaques.<sup>50</sup> It is characterized histologically by parakeratosis, acanthosis, and elongation of rete

Fig. 59.10: Circinate balanitis.

ridges. Dermal capillaries are enlarged and increased numbers are present together with a mononuclear cell infiltrate, and some evidence of extravasation. These changes are similar to those of pustular psoriasis. Circinate balanitis may occur with or without other features of Reiter syndrome. In one series, 9 of 17 patients had balanitis alone. The association with HLA B27 was observed in 15 of these patients.<sup>69</sup>

A complementary use of topical tacrolimus in 3 cases of circinate balanitis not responding satisfactorily to systemic antirheumatic drugs is reported.<sup>70</sup>

### Adverse Drug Reactions

Fixed drug eruptions have a predilection for the glans penis, and are commonly related to therapy with antibiotics, especially tetracyclines and sulfonamides. Other offending drugs include analgesics and anticonvulsants. Lesions are usually present as well-demarcated erythematous areas, which may be bullous and subsequently get ulcerated (Fig. 59.11).<sup>16</sup> This can occur on the first exposure to a drug. Repeated exposures will precipitate new lesions at the initial site (this helps to even confirm the diagnosis). Though the reactions usually occur with chemically related drugs, tetracycline induced eruptions may not recur on challenge with doxycycline. Most lesions fade spontaneously without treatment, but may leave an area of residual hyperpigmentation. Occasionally, treatment with topical, or rarely, systemic steroids may be required.<sup>71</sup> Identification and

Fig. 59.11: Fixed drug eruption.

avoidance of the offending drug are essential to avoid recurrences. Stevens–Johnson syndrome and toxic epidermal necrolysis are serious adverse drug reactions predominantly affecting mucous membranes including genital mucosa. Symptoms begin with burning sensations, target lesions, necrosis of mucous membrane of glans penis/prepuce leading to severely painful erosions covered by necrotic epithelium, and fibrin and/or hemorrhagic crusts. Scarring of mucosal sites is a frequent late complication leading to obliteration of the fornices and strictures. Stopping suspected drug at the earliest, halting the progression of disease, and supportive care are the cornerstones of treatment.

### Bullous Disorders

Mucosal involvement including that of genital mucosa is common in pemphigus. This autoimmune bullous disorder may cause erosions resembling balanitis. Pemphigus vulgaris can cause the clinical picture of balanitis xerotica obliterans and pemphigus vegetans, a rare variant, manifests as vegetating plaques. The lesions usually occur in intertriginous areas but may also affect the glans penis. Rarely, bullous pemphigoid, linear IgA disease, and mucous membrane pemphigoid may cause erosion and scarring simulating balanitis. Treatment depends upon severity of the disease which generally includes systemic immunosuppressives apart from topical corticosteroids.

### Erythroplasia of Queyrat

This is a manifestation of carcinoma *in situ*, which was described by Queyrat in 1911. It has a characteristic red, velvety appearance with sharp margins and a granular surface, usually occurring in uncircumcised men over 40 years of age. The lesions may be single or multiple, and if keratotic or indurated suggest the development of frank SCC. A definite diagnosis is made by a biopsy showing the typical histological picture of intraepidermal carcinoma *in situ*. Early invasion should be excluded by obtaining several biopsies. Transformation of erythroplasia into SCC has been reported to occur in 10–33% of cases.<sup>72</sup> There are various treatment options including 5-fluorouracil, cryotherapy, carbon dioxide laser, or surgical excision. Circumcision is recommended and close follow-up advised.<sup>68</sup>

### Miscellaneous

A wide range of infectious, neoplastic, and inflammatory dermatoses can affect the male genitalia. Several common diseases may involve the genital region only incidentally, while others present in this region with unusual features. In addition, there are some conditions that are entirely or predominantly confined to these regions.<sup>73,74</sup>

Papulonecrotic tuberculid present as chronic, recurrent, discrete, dusky red, inflammatory, papular eruptions leading to ulceration, crust formation and scarring of glans penis (Fig. 59.12). The lesions respond satisfactorily to antitubercular therapy. Biopsy and tuberculin testing should be carried out in all doubtful cases: a therapeutic test is usually decisive.<sup>75</sup>

**Fig. 59.12:** Papulonecrotic tuberculid.

Porokeratosis involving the genital area is uncommon and can occur as part of generalized involvement or as localized porokeratosis that is confined to the genital area. Lesion over glans penis is characterized by centrifugally spreading patches, which are surrounded by a ridge-like border with central atrophy. Treatment of localized genital porokeratosis includes cryotherapy, carbon dioxide laser, surgery, topical 5-fluorouracil, imiquimod, or topical diclofenac.<sup>76</sup>

Cutaneous leishmaniasis involving genitalia is rare. It is characterized by chronic localized ulceration developing at the site of inoculation. The diagnosis is confirmed by demonstrating the presence of *Leishmania* amastigotes in smear or biopsy material. Post-kala-azar dermal leishmaniasis present as papules and nodules over glans penis/prepuce in addition to involvement of other body sites. Treatment is usually either systemic or local pentavalent antimonial therapy depending on the species and clinical picture.

Patients with lepromatous disease and rarely tuberculoid leprosy occasionally develop skin lesions of the penis and scrotum that might be confused with a sexually transmitted infection. Genital involvement is seen in up to 6.6% male patients with leprosy.<sup>77,78</sup> Patients with lesions over penis in type 1 reaction (reversal reaction) may present as phimosis.<sup>79</sup> Treatment is with WHO-recommended multidrug therapy.

Cutaneous larva migrans is a self-limiting dermatitis commonly known as “creeping eruption,” because of its distinctive feature that the lesion creeps or migrates caused by the presence of a moving parasite in the skin. Cutaneous larva migrans has a worldwide distribution though it is common in the tropics and subtropics. The initial lesion starts as an erythematous itchy papule. Soon, a slightly raised flesh colored swollen lesion about 2–3 mm thick develops and forms linear, serpentine (serpiginous), or bizarre tracts. Very few cases are reported involving male genitalia. Albendazole is used in the dosage of 400–800 mg/day for a period that may vary from 1 to 7 days.<sup>80</sup>

Nonvenereal sclerosing lymphangitis of the penis is an infrequent process that affects the distal lymphatics of this organ. It is characterized by the sudden appearance of a translucent and indurated cord on the coronal sulcus (Fig. 59.13). Its etiology

**Fig. 59.13:** Non-venereal sclerosing lymphangitis of the penis (suggestion of a second corona).

**Fig. 59.14:** Pearly penile papules.

is unknown, although it has been related to microtraumas in the area after intense sexual activity. It is a benign, self-resolving process.

Pearly penile papules are normal, asymptomatic anatomic structures located on the proximal glans penis, often appear as skin-colored 1- to 2-mm, discrete, domed papules around the entire corona (Fig. 59.14). Sometime malformations like lymphangioma can lead to edema of penis and structural deformities including phimosis (Fig. 59.15)

## Role of Skin Biopsy

Patients with balanitis and balanoposthitis may present to various specialties such as dermatology, urology, or STD/GUM clinics. Balanitis is the clinical presentation of varied diseases of the genitalia including infectious lesions, inflammatory and neoplastic conditions, and genital involvement in several dermatological diseases. In most cases, a clinical diagnosis is reached without the need for a biopsy. Nevertheless, penile biopsy is safe and may help to confirm the diagnosis. In a retrospective case-note study from UK on 71 patients referred to the biopsy clinic with persistent genital lesions over a 12-month period, 47 biopsies were performed (71% biopsy rate). Forty-three specimens (92%) were appropriate for histopathological diagnosis. Of these, 15% were lichen planus, 15% LS, 10% psoriasis, and 7.5% each had eczema, Zoon, and non-specific balanitis. The remainder represented a variety of other conditions. In 27 cases (68%), the

**Fig. 59.15:** Lymphangioma circumscripsum scrotum causing saxophone penis.

clinical diagnosis was consistent with the histological result.<sup>81</sup> The average biopsy rate for the diagnosis of non-specific balanitis in 14 UK GUM clinics was reported to be 21.5%.<sup>82</sup> An empirical first treatment, with simple emollients before biopsy, appears to be a safe clinical approach for the treatment of non-specific balanitis. A multidisciplinary approach (GUM physicians, dermatologists, urologists, and histopathologists) could help prevent unnecessary biopsies and improve correlation between clinical and histological diagnosis in these cases. In one series, 60 patients with unresponsive penile dermatoses underwent biopsy, of whom 26% had a non-specific dermatitis, 23% HPV infection, and 15% LS. The original clinical diagnosis was confirmed in 33% of cases and the biopsy was not diagnostic in only 3% of cases.<sup>83</sup>

## Conclusion

The causes of balanitis and balanoposthitis are diverse and include inflammatory dermatological disorders, such as lichen planus, seborrhoeic dermatitis, and psoriasis; premalignant conditions including Bowen disease and penile intraepithelial neoplasia; various infections and contact allergies; and Zoon balanitis. Many balanitides prove difficult to diagnose and any condition, which persists despite treatment, warrants further investigation including penile biopsy to confirm the diagnosis.

## Non-venereal Penile Dermatoses

Christopher B. Bunker

### Introduction

Non-venereal skin problems are common in genitourinary clinics. There is a widespread belief that skin diseases of the male genitalia are poorly understood, difficult to diagnose, and unsatisfactory to treat. However, careful dermatological history taking, complete cutaneous examination, and sometimes a skin biopsy usually allow accurate diagnosis and satisfactory medical and surgical management in most cases.

Although stating the obvious, it is worth remembering that the whole skin organ is concerned with sexual expression and activity. The penis is the male structure most commonly deployed in sexual intercourse and it is also the conduit for urinary excretion. The scrotum is the extracorporeal sack for the containment of the testes at the ideal ambient temperature for spermatogenesis. The inguinal folds are intertriginous sites where two layers of skin come into close apposition and function as a part of the hinge between the lower limbs and the trunk. The perineum separates the penis from the anus and the perineal skin is tightly tethered to the underlying tissues.

There are several thousand named skin diseases. This fact is partially explained by considering the pathological possibilities due to the principal morbid processes including neoplasia, inflammation, infection, degeneration, and fibrosis. Their impact on as heterogeneous an organ as the skin with its different cell types, organ structures, and its wide regional, racial, sexual, and physiological variation probably explains this diversity. The genital area differs between the sexes being a good example of regional human variation. The important differences from other sites are that the perineal area is plentifully endowed with functional eccrine and non-functional apocrine sweat glands and holocrine sebaceous glands usually in association with hair follicles but also occurring as free glands (Tyson glands) at some sites such as around the coronal sulcus.<sup>1</sup> These secretions lubricate the hinge between limb and torso, protect the epithelia from irritation, and lubricate the penis for sexual activity primarily in the retraction of the foreskin more than for the penetration of the vagina. The pattern of keratinization of the epithelium also differs throughout

the anogenital area. This is most marked at the mucosal junctions, the prepuce, distal penile shaft, and especially the glans in the circumcised subject. Men have a different pattern of pubic hair when compared with women.<sup>2</sup> The distribution of hair varies widely between men, but in general, the natal cleft, perianal skin, distal penile shaft, prepuce, and glans are devoid of hair. The most common racial variation is pigmentation. The amount of pigment in the skin is related to the amount of melanogenesis and not the number of melanocytes. Melanin synthesis by melanocytes is not only racially determined (constitutive pigmentation), but also induced by sunlight (facultative pigmentation), and circulating and local melanotropic factors (e.g., as part of the cellular response to inflammation). Most races keep the genital skin covered so the later factor is rarely relevant. Physical signs, particularly of inflammation, are harder to detect in deeply pigmented skin. Race may also account for differences in hair type and distribution.

### Normal Variants

Skin tags, naevi, non-viral papillomas, comedones (Fig. 60.1), and hemangiomas may all be regarded as normal variants and are frequently found in the genital area.<sup>1-3</sup> Skin tags are extremely

**Fig. 60.1:** Comedones on shaft of the penis.

**Fig. 60.2:** Seborrheic keratoses on scrotum and shaft of penis.

**Fig. 60.3:** Sebaceous gland prominence.

common in the groins especially of obese men. They may catch on clothing, bleed and get infected. Treatment is by electrocautery or scissor excision and cautery. Seborrheic keratosis, a benign skin tumor, rarely, may occur on the genitals (Fig. 60.2). It may mimic papillomavirus (HPV) infection. Larger, fleshier and more edematous skin tags should arouse the suspicion of Crohn disease. Basal cell papilloma is the most common benign human skin tumor. Single to multiple, flesh colored to black, smooth papule to verrucous plaque, it has a wide differential diagnosis but is frequently mistaken for a viral wart, naevus or bowenoid papulosis. Cullen (1962) reported an incidence of approximately 15% of males having at least one melanocytic naevus (mole) on their genitalia (9.5% in whites; 21.5% in Latins; and 3.5% in blacks).

Sebaceous gland prominence (Fig. 60.3), Tyson glands, sebaceous hyperplasia, ectopic sebaceous glands are all common normal variants of the skin of the scrotal sac and penile shaft but may cause inordinate concern to patients. Pearly, pink, penile papules are common and may be found in up to 15–20% of men, presenting as flesh colored, smooth, rounded papules (1–3 mm) occurring predominantly around the coronal margin of the glans, often arranged in rows or rings (Fig. 60.4).<sup>4</sup> Approximately 35% men will have pearly penile papules in the third decade of their life.<sup>5</sup> A higher prevalence has been reported in black and circumcised men. They can be mistaken for warts by both patients and physicians and are a reason for anxiety for adolescent boys and young adults. In some studies, a relationship with human papillomavirus has been suggested; however, in later work it has been repeatedly confirmed that there is no causal relationship.<sup>6</sup> Histologically, they are angiofibromas. Reassurance usually suffices but cryotherapy or CO<sub>2</sub> laser can be used.<sup>7</sup>

**Fig. 60.4:** Pearly penile papules.

Angiokeratomas (of Fordyce) are less common and are blue to purple, smooth papules on the scrotum or penile shaft that appear and multiply during life (Fig. 60.5).<sup>8</sup> They may cause concern by bleeding. Sometimes they have been misdiagnosed as Kaposi sarcoma or bacillary angiomatosis. The angiokeratomas of

**Fig. 60.5:** Angiokeratomas of Fordyce.

Anderson–Fabry disease (angiokeratoma corporis diffusum) are smaller, less hyperkeratotic pinhead lesions that are found more extensively around the lower limb girdle and upper thighs, from the navel to the knees.

## Circumcision

The prevalence of circumcision in any population reflects racial, religious, and cultural differences. The possible benefits of circumcision may be a lower incidence of inflammatory disease, especially lichen sclerosus and Zoon plasma cell balanitis, as well as protection against sexually transmitted infections including HIV. The foreskin is of variable length and retractability in uncircumcised men. Phimosis refers to partial or complete loss of retractability of the prepuce. It may result from disease processes like lichen sclerosus, lichen planus, and cicatricial pemphigoid.<sup>1,2,9</sup> Paraphimosis describes the situation where the foreskin has become fixed in the retracted state (Fig. 60.6).

## Dermatological Diagnosis

The symptomatic presentation of skin disease is limited. Essentially, patients complain of itch, soreness or pain, a rash, a lump, bump or breach of the skin, or of a problem with hair or nails. The

**Fig. 60.6:** Paraphimosis.

nature of the symptom(s) should be explored, especially the time and space relationships. Patients with anogenital skin complaints are often worried about sexual transmission so a sexual history is vital. The past medical history, especially of skin disease, is important as is the family history. Asthma, hay fever, or eczema in a patient or first degree relative defines atopy. Smoking is a risk factor for cancer of the penis as is poor genital hygiene, but on the other hand the pernicious effects of over-washing with soap are not widely appreciated. Patients may not know what psoriasis is, so it is important to explain. They should be asked about dandruff, cradle cap, warts, and skin cancer. An obsessive drug history is mandatory including that of cough medicines, laxatives, painkillers, and vitamins. When people develop a genital skin problem, they are often frightened that they have contracted a sexually transmitted disease. They then frequently resort to highly unsuitable topical preparations like detergents, disinfectants, and antihistamines. They may have also been misdiagnosed and given an inappropriate prescription by another physician like potent topical corticosteroids or creams containing common allergens. The whole body of the patient should be examined in good light, preferably natural sunlight. It is totally inadequate just to examine the genitalia because the common diagnoses will be reached with the assistance of important clues at other sites. The importance of examining the scalp, brows, eyes, ears, lymph glands, elbows, hands, nails, umbilicus, anus, groins, genitals, knees, feet, toes, retracting the foreskin, parting the gluteal and crural folds, parting the meatal lips, doing a rectal examination, and using a magnifying lens cannot be over-emphasized. Note must be made of the distribution of the rash and its morphology. The site of any lump, bump, erosion, or ulcer must be examined and its morphology defined. It is preferable to draw a diagram and/or obtain a clinical photograph.

Wood's light (a source of ultraviolet light at 360 nm) is helpful in the examination in vitiligo, erythrasma and fungal infections, and rarely porphyria. Skin scraping sent for mycology can be helpful. Occasionally, blood tests or imaging are indicated. Investigations for sexually transmitted diseases (STDs) may be necessary. A skin biopsy is highly informative if the pathologist is given the right information and asked the right question(s). Biopsy cannot be a substitute for clinical diagnosis.

## Pruritus

Pruritus is a cardinal feature of most skin diseases. The response to the sensation of itch is to scratch or to rub and both these actions cause skin morbidity in the form of excoriations, often with secondary infection and impetiginization or lichenification. The important pruritic skin diseases that may affect the anogenital region are listed in Table 60.1.<sup>1,2,10</sup> Itch occurring in the absence of specific diagnostic skin lesions is not usually confined to the genital area but, if so, it should not be labelled as psychogenic until all possible alternative causes have been excluded. The intensity with which itch is sometimes perceived in the anogenital area may be a reflection of the disproportionate cortical representation

**Table 60.1:** Important Causes of Anogenital Pruritus

Causes of genital itching in the absence of clinical findings
Symptomatic dermographism
Contact urticaria
Non-immunological (e.g., mechanical friction of pubic hair, topical substances)
Immunological (latex, body fluids)
Incognito disease
Scabies
<i>Candida</i>
Psoriasis
Drugs
Broad spectrum antibiotics, e.g., tetracyclines
Psychogenic

(Reproduced from: Bunker CB. *Male Anogenital Skin Disease*. London: Saunders, 2004).

of sensory input from the region. It may also be part of more general somatization where there is anxiety about sexual exposure to venereal disease and anogenital cleanliness.

Itching and lichenification around the genitalia and scrotum are common presenting problems. Twenty percent of the population is atopic by definition and this predisposition goes hand in hand with a tendency to itch. Xerosis refers to mildly dry and scaly skin; when more severe the term ichthyosis is used. Two percent of people have psoriasis with a tendency to develop lesions at sites of mild trauma (Köebnerization). These and other diatheses may overlap. The phenotypic possibilities thus created constitute a spectrum of susceptibility to skin disorders. The chief exogenous mechanism is irritation and it may cause problems at vulnerable sites regardless of the phenotype. Irritation may be due to sweat, sebum, friction, desquamated corneocytes, dirt, excreta, sexual secretions, clothing, detergents, toiletries, cosmetics, contraceptives, and topical therapies. It is compounded by maceration and other common afflictions such as piles, constipation, straining at stool, diarrhoea, fecal soiling, incontinence, and overwashing.

## Pediculosis

Pediculosis pubis or public lice (crabs) can cause severe pubic and genital itching with little in the way of physical signs unless the hairs are examined very carefully for nits and the base of individual hairs searched with a hand lens for the louse (1–2 mm in size). Sometimes grey-blue macules, *tache bleu* or *maculae caeruleae*, are seen. Classically, there is an itchy, eczematous eruption with lichenification, excoriations, and secondary impetiginization. In hairy men, the abdomen, chest, axillae, and thighs are also involved. Treatment is with a topical pediculocide such as malathion or permethrin and often also a topical corticosteroid/antibiotic combination. Screening for other sexually transmitted diseases should be offered to the patient and partner(s).

## Scabies

Itch is a predominant symptom of this infestation with the mite *Sarcoptes scabiei*. It can be intense and characteristically keeps patients awake at night. Usually, there is a rash of diagnostic distribution and morphology. Some patients with chronic scabies may have itch in the anogenital region only.

## Urticaria and Dermographism

Dermographism is a form of physical urticaria where rubbing, scratching, and pressure causes an itchy urticarial wheal. It may be a factor in some patients with unexplained genital itching.

## Burning Scrotum Syndrome

In this genital dysesthesia syndrome, patients report itching or burning of the genitalia or scrotum, and complain of persistent or variable redness of the scrotal skin.<sup>1,2,11–13</sup> There may be no signs or a striking erythema. The possibilities of misuse of topical steroids, scrotal rosacea urticaria, dermographism, glucagonoma and of zinc deficiency should be considered. Treatments include avoidance of soap, topical menthol laurumacrogols, lidocaine, dothiepin and systemic antihistamines, tetracyclines, low-dose dothiepin, dosulepin, amitriptyline or gabapentin, steroids, and acupuncture.

## Psychogenic

Dermatological non-disease may be the diagnosis where florid symptomatology is not commensurate with the absence or paucity of any primary dermatological signs. Genital symptoms include itching, excessive redness, burning, and discomfort. In some cases, it is so severe as to prevent the patient from sitting down. Dismorphophobia, depression, and psychosis may be present and attempted or completed suicide is a real risk in such patients.

## Hypopigmentation/Depigmentation

The causes of hypopigmentation and hyperpigmentation are given in Table 60.2.

### POST-INFLAMMATORY HYPOPIGMENTATION AND HYPERPIGMENTATION

Both patterns of pigmentary change are possible after acute inflammation and can contribute to the constellation of physical signs observed in chronic inflammation of the skin. These changes usually appear more pronounced in genetically darker skin. Lichen planus, fixed drug eruptions, and recurrent herpes simplex characteristically cause post-inflammatory hyperpigmentation. Genital trauma, as from a zipper injury, can lead to macular pseudolentiginous lesions on the glans and shaft of the penis. Lichen sclerosus and recurrent herpes simplex are the most common causes of post-inflammatory hypopigmentation. Post-gonococcal and post-syphilitic occurrence has been described.

**Table 60.2:** Causes of Hypopigmentation and Hyperpigmentation

## VITILIGO

Vitiligo follows loss of melanocytes probably due to autoimmune destruction. The genitalia are very commonly affected in men and it is quite usual for the genitalia to be the only site involved. Wood's light demonstrates the contrast between the normal and the pigmented skin. Vitiligo may be one aspect of a tendency to other organ-specific autoimmune diseases, such as alopecia areata, halo naevus, lichen sclerosus, pernicious anemia, diabetes mellitus, Addison disease, and thyroid disease. There are no effective treatments for vitiligo. However, topical corticosteroids may arrest the progression of the disease in an active phase.

## LEUKOPLAKIA

This is a term used for a white patch or plaque. It is vital to separate vitiligo, post-inflammatory hypopigmentation, lichen sclerosus, warts, and penile carcinoma *in situ* (PCIS). Rare causes of post-inflammatory hypopigmentation include Peyronie disease<sup>14</sup> and PEMKB.<sup>15</sup>

## LENTIGINES

Pigmented macules appear on the glans and shaft of the penis. They are usually benign. Occasionally, they may be large, with irregular edges, multifocal, variegated pigmentary patterns, arousing concern about atypical melanocytic proliferation and acral lentiginous melanoma. Under these circumstances, they should be biopsied.<sup>16</sup> Histology shows increased basal epidermal pigmentation with or without benign lentiginous melanocytic hyperplasia and increase in basal melanocyte number. Penile melanosis is a good term for lesions without lentiginous hyperplasia. The most common site for Peutz–Jeghers multiple blue-brown macules is the oral mucosa but anogenital lesions do occur. It is an autosomal dominant disorder and the usual association is with benign gastrointestinal polyps, but malignant change in the GI polyps occurs in 2–3% of cases. Melanoma rarely can arise on the penis. Irregularly delineated, irregularly pigmented, coalescent macular hyperpigmentation should arouse the suspicion of acral lentiginous melanoma. Melanoma is in the differential diagnosis of all pigmented or amelanotic papules or nodules, but penile melanoma is very rare.

## Inflammatory Dermatoses

Patients complain of a scaly or suppurative rash which may or may not be itchy or sore, spontaneously or with sex. On examination, scaly or non-scaly red patches may be seen. Scales do not readily form on the mucosa. Erythroplakia is an alternative term for a red patch on the mucosa and is in common use in oral medicine. Intertrigo is the name given to any dermatosis occurring in skin folds and is susceptible to secondary infection, especially with *Candida*. Balanitis describes inflammation of the glans penis. Balanoposthitis means inflammation of the glans and prepuce and can be regarded as a special form of intertrigo.

By definition, balanoposthitis does not occur in the circumcised male. The causes of balanoposthitis are given in Table 60.3.<sup>17</sup>

## Eczema and Dermatitis

Eczema is not a diagnosis but refers to the same clinical consequences of several different pathomechanisms in the skin. The symptoms and signs vary with the chronicity of the process. The terms eczema and dermatitis may be used synonymously. Eczema is subdivided into endogenous (e.g., atopic, varicose, seborrheic, etc.) or exogenous (contact eczema).

### IRRITANT CONTACT DERMATITIS

This has been alluded to earlier. Management is directed at re-education and behavior modification. The irritants should be identified and eliminated or reduced. Advice must be given about soap substitutes, moisturizers, towels, and toilet paper. Topical corticosteroid ointments with or without antibiotic and anticandidal agents are employed to control the local disease. Antihistamines by mouth are useful. Topical local anesthetics should be avoided because of the risk of sensitization. Secondary infection may require oral antibiotics. A more acute picture characterized by itch, burning or pain, swelling, erythema, and even vesiculation may occur if chemicals of high irritancy or in high concentration are accidentally or deliberately (not uncommon when patients are frightened about the risk of STDs) used on the genitalia. The differential diagnosis can include HSV or fixed drug eruption. Treatment is with soaks of potassium permanganate, very potent corticosteroid creams (sometimes systemic corticosteroids), and systemic antibiotics.

### ALLERGIC CONTACT DERMATITIS

This comes about by contact-induced type IV cell-mediated hypersensitivity after prior sensitization to the agent concerned. The symptoms are pain, burning or itching and the signs are of acute (erythema, swelling, vesiculation) or chronic (erythema, scaling and lichenification) eczema appearing about a week after first contact with the allergen, or within a few hours or longer if already allergic. Identify the allergen and its likely source

**Table 60.4:** Allergens of Relevance to Anogenital Contact Dermatitis<sup>2</sup>

(Table 60.4), and then achieve its elimination. Patch testing is required. Some cases can persist even after the withdrawal of the allergen. Soap substitutes, moisturizers, and potent topical corticosteroids are required in the acute phase, and sometimes oral antihistamines, antibiotics, and corticosteroids. More immediate symptomatology, acute erythema, and angioedema, suggests a contact urticaria which can occur with some of the rubber constituents of condoms and gloves (Fig. 60.7).<sup>18–21</sup> The reaction can amount to anaphylaxis and is a medical emergency. Therefore, prick or patch testing should be performed cautiously. The most common relevant contact sensitivities are due to rubber, contraceptives, medicaments, and toiletries. An increasing problem has been the development of allergic sensitivity not only to preservatives and antibiotics in dermatologically approved topicals, but also to the corticosteroid moiety itself.

**Fig. 60.7:** Angioedema of penis due to contact sensitivity to condom.

## ATOPIC DERMATITIS

Atopic dermatitis (AD) is a common dermatosis, and is associated with a personal and familial predisposition to dry skin and other atopic diseases such as rhinitis, asthma, and conjunctivitis. Twenty percent of the population may be atopic and up to 10% of children may get atopic eczema presenting as itchy, red scaly lesions on the face and flexures from the age of about 2 months. It can be the cause of considerable morbidity. However, the majority (95% by 15 years) of the children do grow out of the disease. Genital disease due to AD is not uncommon but rarely occurs in isolation. Itching at night, lichenification, excoriations with secondary impetiginization, lichen simplex, and even nodular prurigo may occur. Patients have to be careful about irritation and allergy from condoms and chemical contraceptives. AD is a clinical diagnosis. A biopsy is not necessary. Attention to personal hygiene to avoid irritants such as found in soap and some medicaments is crucial. Similarly, common allergens should be avoided and suspected in cases of unexplained regional exacerbation. Treatment (Table 60.5) depends on using the lowest potency topical corticosteroid capable of containing the disease. Topical calcineurin inhibitors are increasingly useful. Combinations containing antibiotic and anticandidal agents are popular at anogenital sites, but there is a real risk of provoking allergic contact hypersensitivity. Systemic antibiotics are needed frequently for generalized flares or localized complications. Oral antihistamines may be useful at night. Systemic corticosteroids are avoided unless at times of real crisis. Phototherapy is not routinely used for genital skin disease because of the increased risk of skin cancer at this site.

## LICHEN SIMPLEX

Lichen simplex presents as itchy, red patches or plaques of lichenified skin and is common on and around the male genitalia (Fig. 60.8) including the penile shaft and scrotum (Fig. 60.9). The skin may be broken by excoriations and become secondarily impetiginized or colonized by *Candida*. Treatment is mostly medical and only rarely surgical removal of a nodular lesion of lichen simplex may be required.<sup>22</sup>

**Fig. 60.9:** Lichenification and edema of penis and scrotum in lichen simplex chronicus.

## SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a very common pattern of eczematous disorder that probably results from a diathesis of abnormal hypersensitivity to the normal commensal cutaneous yeast,

**Fig. 60.10:** Erythematous scaly lesions of seborrheic dermatitis on glans and prepuce.

*Pityrosporum ovale*. Patients complain of a red scaly appearance of the skin (Fig. 60.10). Itching is mild, there is slight erythema, slight to moderate scaling and often folliculitis. The scalp, ears, glabella and brows, nasolabial folds, axillae, chest, and back are also commonly involved as are the groins and penis. Careful examination of these sites supports the diagnosis. Some patients may also have a tendency to develop psoriasis (sebopsoriasis). Their signs may be more florid and other physical signs of subtle or overt psoriasis may be seen on careful assessment. Seborrheic dermatitis is a cutaneous manifestation of HIV infection when it can be very severe and generalized even amounting to erythroderma. Its severity is increased with CD4+ lymphocyte counts below 100/ $\mu$ L. Scrapings can be examined for fungi to exclude tinea and to demonstrate *Pityrosporum* spp. in large numbers. Treatment may not be required by all. However, treatments that suppress the commensal *Pityrosporum* load and reduce irritation and eczematization can be successfully and safely used long term. These include topical antifungals, such as clioquinol, nystatin, and imidazoles, as ointments, creams, lotions, or shampoos. Mixtures of the same agents with mild and moderately potent topical corticosteroids can be used alongside emollients and soap substitutes. Topical calcineurin inhibitors are also effective. In severe cases, such as with concomitant seborrheic folliculitis or in HIV, a course of, or continuous, oral ketoconazole and/or an oral tetracycline might be indicated.

## Psoriasis

Approximately 2% of the population is said to have psoriasis but the diathesis may be much more widespread depending

on the clinical weight given to hesitant and uncertain family histories, vague personal histories of prior rashes, hair and nail problems, and the interpretation of mild scaling of the scalp, ears, elbows, knees, hyperkeratosis of the palms and soles, and nail dystrophy, and pitting. Currently, psoriasis is regarded as a disorder of primary immunodysregulation determined both by a genetic predisposition and environmental triggers (perhaps to streptococcal or other superantigens). These cause the vascular changes, leukocyte infiltration, and epidermal hyperproliferation that are the pathological hallmarks of the disease. The clinical manifestations of psoriasis are of variably itchy, silvery-scaled, erythematous, patches or plaques, which may be guttate, or nummular, in a symmetrical pattern, especially on extensor surfaces. Sometimes a pustular type is seen especially on the palms and soles. The scalp, ears, and umbilicus (and face in sebopsoriasis) are involved, as is the anogenital skin, especially the sacrum, buttocks, pubic mound, shaft of penis, and the glans of the circumcised male (Fig. 60.11). The Köebner phenomenon, which is defined as the appearance of a skin disease at the site of trauma or of another skin disorder, may contribute to this distribution. It is worth stressing that anogenital sites may be the only involved site. Nail changes in the form of pits, onycholysis, and subungual hyperkeratosis may accompany psoriasis. Inverse pattern psoriasis refers to the appearance of the disease on intertriginous skin in the natal cleft, the gluteal folds, the groins, under the dependent, flaccid penis and in the preputial sac and on the glans of the uncircumcised male (where the epithelium is also unkeratinized). Inordinate itch would make one suspicious

**Fig. 60.11:** Psoriasis of glans and shaft of penis.

of tinea and a scraping should be examined and cultured for fungi. Soreness supervenes with superinfection, especially with *Candida*. Some drugs may trigger or worsen psoriasis, including lithium, beta-blockers, antimalarials, and angiotensin-converting enzyme inhibitors. Psoriasis may worsen or appear for the first time in the HIV-infected patient. Pustulosis may predominate and occasionally psoriasis is the cause of an erythroderma. Again anogenital lesions are common and frequently disabling. Usually, the diagnosis is clinical but a biopsy might be necessary for the solitary mucosal lesions in the uncircumcised, where Zoon balanitis and erythroplasia of Queyrat enter the differential diagnosis. Topical treatment relies on emollients, soap substitutes, corticosteroids combined with antibiotic and antifungal agents or weak tar solutions. Strong, crude tar preparations should be avoided. Dithranol, because of its irritant potential, is usually avoided in this region. The vitamin D analog calcipotriol can be helpful as can calcineurin inhibitors. Severe anogenital, inverse psoriasis can be an absolute indication for systemic treatment with drugs like methotrexate or cyclosporin. Phototherapy is contraindicated because of the risk of genital cancer.

### Reiter Disease

Reiter disease or syndrome is part of the same continuum as psoriasis in genetically predisposed individuals. Reiter syndrome is defined as arthritis, urethritis, and conjunctivitis.

It is precipitated by non-specific urethritis or bacillary or amoebic dysentery and associated with HLA B27. The clinical features, radiological signs, diagnosis, and management are discussed in Chapter 65. Skin lesions in Reiter syndrome may be similar to those of psoriasis. Classically, patients with Reiter disease may have thickened yellow palms and soles with a cobblestone appearance with or without pustular lesions (keratoderma blennorrhagica) and involvement of the penis (circinate balanitis, Fig. 60.12); but they may also have any of the features of psoriasis described above. Arthritis (oligoarticular) is an important component. Penile lesions have the same histopathology as psoriasis. Reiter disease has been reported with increased frequency in patients with AIDS

**Fig. 60.12:** Circinate balanitis.

and also in the earlier stages of HIV infection in its classical or incomplete form. Treatment is similar to that for psoriasis. Genital lesions seem to be curiously responsive to topical calcineurin inhibitors. Oral retinoids are useful especially in HIV-infected patients.

### Zoon Plasma Cell Balanitis

Zoon plasma cell balanitis is a disease of the uncircumcised man. It does not occur on the keratinized penile shaft or foreskin of an uncircumcised men and is not seen in circumcised men at all. However, it has also been reported to afflict the vulva, mouth, lips, and epiglottis. The presentation is of indolent and relatively asymptomatic, well-demarcated, glistening, moist, shiny, bright-red or brown patches seen anywhere over the glans and prepuce (Fig. 60.13). Dark red stippling, "cayenne pepper spots," is due to hemosiderin deposition. Solitary or multiple lesions of differing sizes (guttate or nummular) may be seen, which characteristically "kiss." The etiology of Zoon balanitis is unknown, but its occurrence in the uncircumcised suggests an irritant or hypersensitive response to retained smegma (desquamated keratinocytes and secretions), commensal and/or opportunistic micro-organisms and urine. Chronic infection with *Mycobacterium smegmatis* has been postulated. Trauma, heat, poor hygiene, and mild urinary incontinence may be the factors. The most important differential diagnoses are erythroplasia of Queyrat or intraepithelial carcinoma *in situ* of the penile mucosa, erosive lichen planus, Kaposi sarcoma, psoriasis, and seborrheic

**Fig. 60.13:** Zoon balanitis. Glans and prepuce. "Butterfly" or "kissing" lesions. Reproduced with permission from: male anogenital skin diseases, Ref. 2.

**Fig. 60.14:** Zoon balanitis. The key features are erosion, ulceration, vascular ectasia and congestion with no intact epidermis on the surface. Beneath this there is edema and a band-like chronic inflammatory infiltrate, which is heavily populated by plasma cells. Some fibrosis is also apparent. Reproduced with permission from: Male anogenital skin diseases, Ref. 2.

dermatitis. Others include secondary syphilis (all patients should be screened for sexually transmitted disease), tinea, contact dermatitis, and fixed drug eruption. It is important to realize that Zoon balanitis may not be a primary dermatosis but rather a reactive process indicative of a dysfunctional foreskin.<sup>1,2,23</sup> Careful examination for an underlying primary dermatosis should be carried out. A biopsy is advised in most cases and the pathologist should be asked to look for concomitant disease like lichen sclerosis. Zoon balanitis has distinctive histologic findings. Epidermal atrophy with complete effacement of the rete ridges is present. Ulceration may occur. Diamond-shaped “lozenge keratinocytes” are common with uniform intercellular spaces termed watery spongiosis. A dense lichenoid sub-epidermal infiltrate composed largely of plasma cells is characteristic (Fig. 60.14). Erythrocyte extravasation and hemosiderin deposition are often noted. Although the condition may improve with enhanced hygiene and the intermittent application of mild or potent topical corticosteroid (+ antibiotics and anticandidals), and topical calcineurin inhibitors. Zoon balanitis usually persists or relapses. Definitive curative treatment is circumcision.

## Lichen Sclerosis

Penile lichen sclerosis may be asymptomatic. However, diverse, often vague, symptomatology is usually encountered. Patients may describe itching, burning, bleeding, hemorrhagic blisters,

**Fig. 60.15:** Atrophic, white patches of genital lichen sclerosis.

discomfort with urination and narrowing of the urinary stream. They may be concerned about the changing anatomy of their genitalia. The predominant symptomatology is of difficulty with sexual intercourse. The usual cutaneous presentation of lichen sclerosis is of atrophic white patches or plaques (Fig. 60.15). However, lilac, slightly scaly patches with telangiectasia and sparse purpura, bullae, erosions and ulceration may be encountered. Other presentations are phimosis, paraphimosis, urinary retention, and even renal failure. Anogenital lichen sclerosis is more common than extragenital or oral disease. Rarely, there may be concomitant involvement of these sites. In adults, anogenital lichen sclerosis is said to be about ten times more common in women than men. Perianal disease is very rare in the male. Lichen sclerosis may be much more frequent than is generally supposed in young boys. Persistent primary phimosis or the secondary development of phimosis in a previously retractable foreskin should be viewed with suspicion: some, many or most of such cases will be due to lichen sclerosis. Whereas posthitis xerotica obliterans refers to chronic damage to the prepuce by lichen sclerosis, balanitis xerotica obliterans (BXO) is a more frequently encountered term describing severe damage from long-standing, sometimes undiagnosed, unchecked disease. BXO can be a consequence of other scarring dermatoses such as lichen planus and cicatricial pemphigoid. The evidence indicates that male genital lichen sclerosis (MGLSc) is due to chronic occluded exposure of susceptible epithelium to urine. MGLSc never occurs in men who were circumcised at birth; is associated with trauma, instrumentation, genital jewelry (piercing), and gross anatomical abnormalities (e.g., frank hypospadias); recurs in grafts; and never causes perianal disease (in striking contradistinction to women, the male perineum is never chronically exposed to urinary irritation).<sup>1,2</sup> The arrangement of the distal urethra, navicular fossa, and meatus has evolved to function as a low-pressure valve. The embryology is complicated, and a wide variation in naviculomeatal valve structure and function is revealed by meticulous clinical assessment. Many men presenting with genital lichen sclerosis mention dribbling after voiding and have abnormal naviculomeatal morphology on examination. In these men, urine dribbling from the meatus after the prepuce has

been replaced following voiding will spread widely between the juxtaposed mucosal surfaces. Occlusion and the phenomenon of koebnerization create the inflammation.

Female genital lichen sclerosis seems to spare non-cornified stratified squamous epithelium and women do not have urethral disease. In men, susceptibility to the irritant effects of urine may be due to variability in the epithelialization of the mucosa of the distal urethra and navicular fossa, as well as their dysfunction as a valve. The definition of mucosa is controversial but indubitably the proximal penile urethra possesses a true mucosa, while the circumcised glans certainly does not, the uncircumcised glans and inner prepuce probably do not, and the outer prepuce does. There are transition zones between true urothelium and true skin. Just as there is wide variability in the size and shape of the navicular fossa, there is probably variability in the site of the epithelial transition zones, the degree of keratinization of the glans, the length and, thus, surface area of the foreskin, and the disposition of adnexa. Perhaps urethral lichen sclerosis eventuates because the transition to stratified keratinizing squamous epithelium occurs and/or urethral mucus glands are lost, too proximally, thus rendering the epithelium focally susceptible to the pernicious irritant effects of urine.<sup>1,2,24,25</sup> However, patients with lichen sclerosis, especially women, have an increased incidence of organ-specific autoantibodies and autoimmune disease. In male genital lichen sclerosis, there is an increased frequency of several class II antigens including HLA DQ7 which also occurs more frequently in women with lichen sclerosis. One study has found HPV (types 6, 16, and 18) in 70% of boys with lichen sclerosis, but the overall clinical impression of lichen sclerosis is that it is not a communicable disease. Most cases of lichen sclerosis can be diagnosed clinically.

Sometimes lichen planus and cicatrizing pemphigoid may raise diagnostic difficulties. If there is clinical doubt, then a biopsy should be done. A biopsy is mandatory if the lesion or a part

**Fig. 60.16:** Lichen sclerosis showing the typical small vessel dilation within the bland and loose edematous hyaline stroma beneath the epidermis and, beneath that, patchy aggregates of chronic inflammatory cells. Courtesy: Nick Francis, London, UK. Reproduced with permission from: male anogenital skin diseases, Ref. 2.

is eroded or verrucous. Histology initially shows a thickened epidermis, followed by atrophy and follicular hyperkeratosis. This overlies an area of edema with loss of the elastic fibres and alteration in the collagen, which in turn overlies a perivascular band of lymphocytic infiltration (Fig. 60.16). Hemorrhagic vesicles occur when the edema causes detachment of the epidermis with capillary erosion and extravasation of blood. Very potent topical corticosteroid used under supervision is an effective treatment. This appears to induce remodeling of the affected mucosa, relieve phimosis, improve the histological signs, and save the organ from circumcision. Confounding secondary candidal and bacterial infection should be treated. Testosterone propionate ointment and oral stanozolol have been used to debatable effect. Topical calcineurin inhibitors should not be used.<sup>26</sup> Carbon dioxide laser treatment for lichen sclerosis has been reported.

Frenuloplasty, meatotomy, or a sophisticated plastic repair may be necessary. Even if disease involves non-preputial sites it can regress following circumcision. But lichen sclerosis can persist or recur. Squamous cell carcinoma of the penis is the worst possible complication of lichen sclerosis. The risk is possibly less than for vulval lichen sclerosis. A risk of 2–12.5% is suggested by the literature, depending on length of follow-up; the latent period may be 1–3 decades. Verrucous carcinoma (Buschke–Löwenstein tumor) has been associated with previous lichen sclerosis.<sup>1,2</sup> It is not known for certain what impact medical and surgical treatment has on the subsequent incidence of penile cancer. Patients should be followed up long term, especially if circumcision has not been performed or if symptoms persist or recur after any modality of treatment.

## Lichen Planus

Lichen planus is a common inflammatory dermatosis that has a particular predilection for the mucosae and can involve these sites in isolation. The classical extragenital eruption is often intensely itchy and symmetrical, manifesting as flat-topped, polygonal, purple papules, coalescing to form annules and plaques and surtopped by fine, lacy scales called Wickham striae (Fig. 60.17). An aggressive form may lead to a scarring folliculitis of

**Fig. 60.17:** Annular lesions of lichen planus showing Wickham striae.

**Fig. 60.18:** Lichen planus. A medium power view of penile skin showing flattening of the wheaty architecture and underlying lichenoid chronic inflammatory infiltrate with interface inflammation of the basal epidermal layer and associated degeneration. Courtesy: Nick Francis, ICM, London, UK. Reproduced with permission from: male anogenital skin diseases, Ref. 2.

the scalp and a permanent nail dystrophy. Lichen planus can present in the anogenital area, like the classical disease at other sites, as itchy, red-purple papules and also as patches or plaques. Occasionally, an erosive form is encountered and this can be extremely symptomatic leading to severe male dyspareunia. The itchy, monomorphic, flesh-colored, micropapular form, lichen nitidus has a predilection for the penis but rarely in isolation. Most cases of lichen planus are self-limiting, although some patients relapse and remit. Post-inflammatory hyperpigmentation can exist for months or years. Chronic mucosal erosive lichen planus is associated with a risk of progression to squamous cell carcinoma, but most reports concern oral lichen planus. Squamous carcinoma may complicate chronic hypertrophic lichen planus of the lower leg but has also occurred in the context of hypertrophic lichen planus of the glans penis. A biopsy is, therefore, sometimes performed for diagnostic purposes (Fig. 60.18) but is more importantly done in the follow-up of the rare cases of chronic genital disease, where development of ulcerative or verrucous features leads to concern about the development of squamous cell carcinoma. Potent and very potent topical corticosteroids usually suffice for treatment. Patients are told to continue with the treatment until the lesions are non-itchy and flat. They are warned about post-inflammatory hyperpigmentation. Intralesional and systemic corticosteroids are sometimes exhibited for severely itchy disease and erosive orogenital involvement. Topical and oral cyclosporin have been used. Circumcision can cure erosive genital disease presumably by abolishing köebnerizing forces.<sup>27</sup>

### Hailey–Hailey Disease (Benign Familial Pemphigus)

Hailey–Hailey disease is an autosomal dominant disorder of keratinocyte adhesion with gradual onset in young adulthood and a tendency to improvement with age. The clinical features of this disease are moist, crusted plaques or scaly patches studded with pustules and warty papules involving the flexures. Very rarely papular

plaques similar in appearance to genital warts have been reported. The differential diagnosis in the groins is of an intertrigo with Darier disease. The diagnosis is confirmed histologically. The mainstay of treatment is topical corticosteroids and topical antibiotics. Radiotherapy (Grenz rays and electrons), etretinate, and acitretin have also been used successfully. Dermabrasion, excision with grafting and CO<sub>2</sub> laser ablation are other options.

### Darier Disease (Keratosis Follicularis)

Flexural disease is mild in most patients but does occur in the vast majority. The lesions can be very sore and malodorous. The intertriginous features are similar to those of Hailey–Hailey disease. Nearly all patients will have keratotic papules in seborrheic areas, palmar pits, and nail changes in the form of dystrophy, fragility, Union Jack nails—red, white and blue streaks, V-shaped terminal nicks. Sunlight is a known provocation but usually clinically irrelevant in terms of genitocrural disease and bacterial or herpetic superinfection, well-recognized. Biopsy confirms the diagnosis. Topical treatment for Darier disease follows the same lines as for Hailey–Hailey disease. However, a very useful modality in the former is the use of oral retinoids, such as isotretinoin and acitretin. Use of these agents is limited in women of child-bearing potential because of fetal teratogenicity and the risk of side effects due to the hypervitaminosis. A syndrome (especially diffuse idiopathic [misnomer] skeletal hyperostosis). Local radiotherapy to flexural sites has helped some patients and recently CO<sub>2</sub> laser ablation has been advocated.

### Fixed Drug Eruption

Fixed drug eruptions (FDE) are red, swollen plaques sometimes with central blister formation, erosion, and ulceration (Fig. 60.19). The symptoms are itch or burning. The genitalia are classical sites for this, as are the face and extremities. Healing is with post-inflammatory hyperpigmentation. On first exposure, the eruption can take 1–2 weeks to appear, but subsequently appears just a few hours to a few days after ingestion. Recurrence occurs at the same site each time the drug is exhibited, and such rechallenge can be used as a diagnostic test. Causes of FDE

**Fig. 60.19:** Bullous fixed drug eruption.

**Fig. 60.20:** Intertriginous lesions of erythrasma.

are tetracyclines, phenolphthalein, sulfonamides, barbiturates, quinine, and papaverine. A biopsy can confirm the clinical diagnosis. Treatment obviously centers around identification and withdrawal of the offending agent. Very potent topical corticosteroid treatment used in the acute phase may limit the symptomatology and long-term damage.

### Erythrasma

Velvety, red, superficially scaly plaques are found extending symmetrically from the groins onto the upper thighs. In the inguinal folds, erythrasma is an intertrigo and may be macerated and eroded (Fig. 60.20). It is not usually very itchy but can be slightly sore in the groins and may have been present for years. Other sites of predisposition include the axillae and toe web spaces. The causative organism is a gram-negative rod/coccus, *Corynebacterium minutissimum*. Erythrasma is a clinical diagnosis confirmed by coral pink fluorescence under an ultraviolet source (Wood's light), bacteriology, and exclusion of tinea cruris. Topical treatment with clindamycin, erythromycin or an imidazole is effective, but a course of oral erythromycin is definitive and effective at several sites simultaneously. However, erythrasma is prone to recur.

### Candidosis

Candidosis (thrush) presents as an intertrigo or balanoposthitis. Burning and soreness are more likely than itch. Coalescent red patches or plaques involve the folds often with superficial erosions. Pustulosis may extend out onto the skin of the abdomen, buttocks or thighs from the irregularly margined intertriginous lesions. *Candida* of the penis, which appears to have a prevalence of about 10% of that of vaginal candidiasis, has attracted very little research interest. Some have argued that primary *Candida* of the penis does not occur in the immunocompetent man. *Candida* is frequently found as a secondary pathogen in anogenital dermatoses. Eliciting the signs of candidosis does not preclude a thorough clinical search for an underlying dermatological or medical cause. This is because the signs due to *Candida* may be more florid than the underlying cause. Medical causes (Table 60.6) include diabetes mellitus, iatrogenic immunosuppression, and systemic antibiotic treatment. Although it is indisputable

**Table 60.6:** Medical Causes of Candidosis<sup>2</sup>

that oropharyngeal candidiasis is almost invariably found in HIV infection, genital disease is not. It may be overlooked in the face of more pressing symptomatology in other sites or systems. Diagnosis is clinical and supported by direct demonstration of the budding forms of the yeast and pseudohyphae (visualization is enhanced in a potassium hydroxide preparation by a drop of India ink under the cover slip) and microbiological culture.

Underlying disease should be identified and treated and predisposing factors rectified. Treatment includes topical nystatin, clioquinol or an imidazole, often very usefully combined with hydrocortisone or a moderately potent corticosteroid. An oral azole (imidazole or triazole) like itraconazole, fluconazole, ketoconazole may also be indicated. Many HIV-positive patients may be required to take long-term azole antifungals orally.

### Tinea

Tinea or ringworm (Fig. 60.21) refers to superficial dermatophytosis. *Trichophyton rubrum* is the most common

**Fig. 60.21:** Annular lesion of tinea on shaft of the penis.

species responsible. Tinea is a common disease of the pelvic girdle especially of the groins and is not always spread from the feet. People with tinea manuum or unguium can spread it to the groins or feet because they are common sites of chronic itch. Tinea cruris is itchy, and diagnosed in the presence of red-brown, scaly patches with raised, redder edges extending out of the groins and onto the abdomen, buttock and down the thighs. Because of the site, annular lesions are not obvious but can be imagined. Unfortunately, clinical diagnosis is not always straightforward because many patients have been previously misdiagnosed and/or partially treated with topical corticosteroids plus or minus topical antifungal agents. Tinea incognito is the expression given to the presentation in the previously corticosteroid-treated patient where the symptom of itch and the signs of inflammation including the redness, the scale, and the well-demarcated often scalloped, elevated active edge have been suppressed. There will, however, be abundant fungal hyphae, which makes the diagnosis by microscopy (potassium hydroxide preparation of a skin scraping) much easier. Patients partially treated with topical antifungals are harder to diagnose because the signs are attenuated, and there will be few hyphae making microscopy difficult. Culture may be inhibited by the presence of the drug in the specimen. Reevaluating the patient after a few days abstention from topical treatment is often advisable. Other problems are the concomitant presence of erythrasma<sup>28</sup> and the rare occurrence of tinea on the glans penis causing itch, pain and producing an erythematous patch that also involves the scrotum.<sup>29–31</sup> Wood's light examination is sometimes helpful in the diagnosis of more exotic fungal infections and for excluding erythrasma. For treatment, anogenital dermatophytosis often requires oral treatment with griseofulvin, terbinafine or itraconazole. Topical treatments often fail because of the anatomical complexity of the area; difficulty in sustaining complete, protracted, regular coverage of the whole area with a cream or ointment; and because there may be mycosis of feet or hands, toe or finger nails.

## Erosions and Ulcers/Blisters and Vesicles

Causes of erosions, ulcers, and vesicles and bullae have been listed in Table 60.7.

## Genital Trauma

The genitals may be traumatized by sexual activity. The penis is very vascular and hematoma formation is not rare. Sex aids can result in abrasions, eczema, and ulceration.

The penis may be incarcerated by ring device, rubber bands or hair, and strangulation, necrosis and autoamputation may follow. Seriously mentally ill patients have been known to mutilate their genitalia, as have transvestites, but non-psychotic genital self-mutilation can also occur. Australian aborigines slit the penis and open the urethra ventrally, creating a hypospadias and this is called subcision. The penis may

**Table 60.7:** Causes of Erosions, Ulcers, and Vesicles and Bullae<sup>2</sup>

also be traumatized by external urinary devices employed to counter urinary incontinence.

## Dermatitis Artefacta

Dermatitis artefacta focalized to the penis is sometimes encountered. Dermatitis artefacta at other sites is recognized by dermatologists as unexplained erosions or ulcers that fail to heal or inexplicably breakdown despite treatment. The lesions are often geometrical, angulated or rectilinear. Sometimes they are induced by needles, knives, instruments, and cigarettes. Extraneous foreign material may be introduced into the skin. The psychological ambience of *belle indifférence* may be present. There may be depression, but rarely is a major psychiatric illness present. Confronting the patient with the suspected diagnosis is widely regarded as dangerous because of the risk of suicide. Management must be medically and psychologically supportive. Antipsychotic medication such as pimozide may be successful if accepted by the patient.

## Aphthae

Aphthous ulceration of the penis and scrotum does occur, but this is not an acceptable diagnosis in the perianal skin or without overt exclusion of sexually transmitted diseases and other causes of genital ulceration, especially Behçet syndrome.<sup>32</sup> This is completely different from oral aphthae where a clinical diagnosis is acceptable clinical practice. The causes of aphthae are obscure. The histology is non-specific. Treatment is with topical corticosteroid/antibiotic/anticandida combinations.

## Behçet Disease

Behçet disease<sup>32,33</sup> is an inflammatory disorder of unknown cause, characterized by recurrent oral aphthae, genital ulcers, uveitis, and skin lesions. Complex aphthosis,<sup>34</sup> which is considered to be a *forme fruste* of Behçet disease, is defined as the presence of almost constant, multiple (>3) oral or oral and genital aphthae in the absence of systemic manifestations. According to the International Study Group<sup>35</sup> criteria, Behçet disease is diagnosed in the presence of recurrent oral ulceration with any two of the following criteria, i.e., recurrent genital ulceration (Fig. 60.22), uveitis or retinal vasculitis, papulopustular lesions or erythema nodosum or acneiform lesions and a positive pathergy test. There can be involvement of central nervous, gastrointestinal, cardiovascular, pulmonary, and musculoskeletal systems, and kidneys. The pathogenesis of Behçet disease and complex aphthosis is mediated by a combination of factors involving immune dysregulation, inflammatory cytokines and infectious agents in a genetically predisposed individual (HLA B51). The histologic features of Behçet disease are characterized by vasculitis and thrombosis

**Fig. 60.22:** Scrotal and penile ulcers of Behçet disease.

**Fig. 60.23:** Histology of Behçet disease showing leukocytoclastic vasculitis and a dense lymphocytic infiltrate in the dermis.

(Fig. 60.23). The vasculitis may be leukocytoclastic or a lesser degree of neutrophilic vascular reaction with no fibrinoid necrosis. The differential diagnosis of the systemic features of Behçet disease is systemic lupus erythematosus (SLE), relapsing polychondritis (MAGIC syndrome), familial Mediterranean fever, and Reiter syndrome. Treatment is with topical or intralesional corticosteroids, colchicine, thalidomide, rebamipide and dapsone for mild to moderate mucocutaneous lesions. Immunosuppressive drugs (such as systemic steroids and azathioprine) or biological response modifiers (such as infliximab, etanercept, and adalimumab) are indicated for severe mucocutaneous lesions, severe ocular lesions, and in cases of systemic involvement.<sup>33</sup>

## Hidradenitis Suppurativa

Painful genital skin involvement with fibrous bridges, comedones, folliculitis, furunculosis, deep discharging sinuses, nodules, cysts, and scars in the groins (Fig. 60.24) and axillae is pathognomonic.<sup>1,2</sup> The disease may involve the natal cleft and buttocks. It is more common in black subjects. It affects the axilla preferentially in women and the perineum in men. Many patients will also have severe conglobate acne. The morbidity of hidradenitis can be very severe, interfering with sitting, sleeping, walking, defecation, and

**Fig. 60.24:** Discharging sinuses and ulcers of hidradenitis suppurativa.

sexual activity, so depression is common. Hidradenitis suppurativa is considered by some to represent apocrine acne. The role of endocrine factors is unknown. Occlusion leads to comedone formation and purulent infection due to secondary infection with gram-negative and gram-positive organisms. Chronicity carries a risk of squamous cell carcinoma. Hidradenitis is a clinical diagnosis. Swabs should be taken for bacteriological evaluation and to guide therapy.

Rarely, a biopsy may be necessary to exclude carcinoma or Crohn disease. Perineal Crohn disease mimics hidradenitis with its granulomatous inflammation, ulceration, and fistula formation, but it is less painful, the axillae are uninvolved, and it is rare for patients to be free of overt gastrointestinal symptoms. Oral antibiotics such as erythromycin, flucloxacillin, ciprofloxacin, metronidazole, and topical antiseptics offer the lynchpin of management. In men, hormonal manipulation with antiandrogens such as cyproterone acetate is an option, as it is in women. Oral prednisolone can be used as alongside antibiotics to control intercurrent exacerbations. Oral isotretinoin helps only some patients. A breakthrough seems to be offered by treatment with infliximab (and other biological response modifiers). Surgical resection and reconstruction are necessary for extensive, recalcitrant disease, but local excision is also a good treatment for localized disease.

## Crohn Disease

It can affect any part of the gut and its cutaneous borders from the mouth to the anus. Crohn disease of the penis is rare. Metastatic cutaneous ulceration of the penile shaft, multiple scrotal urinary fistulae and destruction of the proximal urethra have been reported.

## Pemphigus

Pemphigus is a group of rare immunobullous disorders where loss of epidermal cohesion causes blistering and erosion of mucocutaneous sites. Therefore, the penis is often involved but not usually in isolation. Diagnosis is by biopsy and immunofluorescence studies. Treatment requires high-dose systemic corticosteroids and often other immunosuppressant medication.

## Ecthyma Gangrenosum

Ecthyma gangrenosum is usually due to *Pseudomonas* septicemia. A red macule rapidly progressing to a blue bulla, rupturing to form a necrotic ulcer with a central erythematous halo; or painful, tense grouped vesicles, which rapidly become necrotic and form ulcers with black necrotic eschars are the clinical characteristics of ecthyma gangrenosum. It occurs in immunosuppressed patients including children and has a predilection for the extremities and anogenital regions. It may affect the penis in isolation leading to gangrene.<sup>36</sup> The prognosis is generally poor. Patients with hematological malignancy may develop the disease without

evidence of *Pseudomonas* septicemia, and in these cases the prognosis is better. The important causes of penile necrosis are given in Table 60.8.

## Pyoderma Gangrenosum

There are a handful of reports of pyoderma gangrenosum involving the penis in adults.<sup>37</sup> It has also occurred on the scrotum. One of the cases was associated with ulcerative colitis and another with chronic lymphocytic leukemia, but the others occurred without any associated disease. Pyoderma gangrenosum is a diagnosis made when other causes of purulent ulceration such

as neoplasia, and artifact have been excluded. It may occur as a Köebner phenomenon to local trauma such as urological surgery. Aggressive therapeutic measures are often required including high-dose oral corticosteroids, intravenous methylprednisolone oral cyclosporine or cyclophosphamide. Minocycline and thalidomide may be beneficial in pyoderma gangrenosum unresponsive to corticosteroids and when associated with Behçet disease. Mycophenolate mofetil and infliximab show promise.

### Herpes Zoster

Sacral and penile herpes zoster is relatively rare, but can be associated with severe morbidity due to nocturia, dysuria, hesitancy, acute urinary retention, constipation, and fecal retention. Painful, grouped crusting vesiculopustular lesions may be found on the buttock, in the perineum, on the scrotum and penis (Fig. 60.25), in the groins, and on the upper thigh. Hospitalization, urological assessment, observation, catheterization, sigmoidoscopy, and possibly, assisted fecal extraction are indicated. Treatment should be with intravenous acyclovir.

### Fournier Gangrene

In 1883, Fournier, a Parisian dermatologist, described five cases of spontaneous genital gangrene and ulceration. Since then several hundred cases have been reported and predisposing factors, clostridial and non-clostridial causative microorganisms have been identified.<sup>1,2,38</sup> Patients present with systemic upset, painful erythematous swelling of the genital, perianal or lower abdominal skin, and some may have urinary retention. An “ominous” black spot may appear on the scrotum. Rapidly, necrosis of skin and

deeper tissues supervenes and death ensues. The mortality may be higher than 50% unless diagnosis is prompt and radical management instituted. There is gross systemic toxicity, and its clinical picture overlaps with necrotizing fasciitis and Meleney gangrene. Risk factors include colorectal disease, diabetes mellitus, alcoholism, anogenital infection, chemotherapy, debilitation, granulocytopenia, HIV, post-instrumentation, post-operative (urological—including vasectomy and colorectal), heroin addiction, trauma, and unusual sexual practices. The process probably begins with appendageal or urethral polybacterial infection, followed by a necrotizing vasculitis affecting skin, subcutis, fascia, and muscle. Radiological studies may show soft tissue gas. The differential diagnosis of Fournier disease includes herpes simplex, streptococcal or staphylococcal cellulitis, streptococcal necrotizing fasciitis, gonococcal balanitis, ecthyma gangrenosum, allergic vasculitis, polyarteritis nodosa, necrolytic migratory erythema, vascular occlusion syndromes, and warfarin-induced necrosis. If the clinical diagnosis of Fournier gangrene is entertained then drastic emergency management is required. Surgical, microbiological, and intensivist assistance are required. Radical surgical debridement of all affected tissue is undertaken and broad spectrum systemic antibiotic therapy initiated. If the patient survives then plastic surgical repair is undertaken. In adults, the mortality is around 25% and is highest in disease of anorectal rather than urogenital origin.

### Tuberculosis

Penile tuberculosis is extremely rare. Primary penile ulceration<sup>39</sup> with or without inguinal lymphadenopathy may occur due to sexual infection or secondary to tuberculosis elsewhere, for example the gastrointestinal system and lung. Not uncommonly, small, punched out ulcerations of papulonecrotic tuberculide occur on the glans penis, and this may be the only site involved (Fig. 60.26).<sup>40,41</sup> Diagnosis is made on the basis of culture and histopathology. Pyoderma gangrenosum, Crohn disease, hidradenitis, neoplasia, artefact,

**Fig. 60.25:** Herpes zoster of shaft of the penis.

**Fig. 60.26:** Papulo-necrotic tuberculide on the glans penis. The lesions on patient's finger are common warts and are unrelated to genital lesions.

sexually transmitted diseases, amoebiasis, and deep mycoses appear in the differential diagnosis. Treatment is by appropriate combination chemotherapy.

## Leishmaniasis

Cutaneous leishmaniasis has been reported on the genitalia.<sup>42</sup> As at other sites, painless papules or pustules progress to chronic ulceration without regional lymphadenopathy. The disease is due to one of several protozoal organisms and is endemic in the Middle East, Asia, and South America. Diagnosis depends on biopsy and identification of Leishman–Donovan bodies. Some lesions may heal spontaneously, but with scarring. Treatment is with the antimonial drug, sodium stibogluconate intravenously.

## Amoebiasis

Cases of amoebiasis presenting as balanitis have been described. Painful swelling and ulceration are the principal clinical features, but frequency, dysuria, and retention may be complications. Most case reports have come from tropical countries, particularly Papua New Guinea. Contamination from an amoebic bowel infection is thought to be the route of infection either by self-inoculation, or by heterosexual intercourse where the female partner has amoebic vaginitis, or by sodomy, which seems the most likely mechanism in Papua New Guinea. Diagnosis is by demonstration of the *Entamoeba histolytica* trophozoites in the mucopurulent discharge or in a biopsy. Treatment is with debridement and oral metronidazole. Sometimes circumcision may be necessary preferably after the diagnosis has been made and antiamoebic therapy initiated.

## Palpable Lesions/Tumors

Inflamed as well as neoplastic tissue can present as palpable lesions (Table 60.9).<sup>1,2</sup>

### Keloid

It has been stated that the skin of the penis never forms keloid, but it has been reported very rarely following circumcision, other surgical procedures, trauma, and burns. Chronic edema resembling keloid on the dorsum of the penis has been reported to complicate the use of a condom catheter for neurogenic bladder.

### Sarcoid

Sarcoid is rare on the genitals but sarcoidosis should be in the differential diagnosis of papules and nodules affecting the penis and scrotum.<sup>43</sup>

## Granuloma Annulare

A few cases of granuloma annulare affecting the penis have been reported. In its localized form, it usually affects the hands and feet perhaps associated with trauma; in its generalized form, it may be associated with diabetes mellitus. Erythematous smooth, round and linear nodules are described.<sup>44</sup>

**Table 60.9:** Palpable Lesions<sup>1,2</sup>

Reddish/flesh-colored papule	Pigmented papules
<b>Non-infective conditions</b>	Skin tags
Lichen nitidus	Basal cell papilloma

	Squamous cell carcinoma
	Malignant melanoma
	Kaposi sarcoma
	Penile metastases
	Chronic lymphocytic leukemia

(Reproduced from: Bunker CB. *Male Anogenital Skin Disease*. London: Saunders, 2004).

## Schistosomiasis

Perineal granulomatous lesions are a rare manifestation of schistosomiasis (*Schistosoma haematobium*), which is endemic in many parts of the world and contracted by swimming in water containing infected fresh-water snails. It may present with skin symptoms and signs at the time of infection or later with hematuria. Rarely, genital skin lesions may lead to the diagnosis. The papules and nodules may be skin colored, pink or brown, scattered or grouped, affecting the penis, scrotum, and vulva. They can spread onto the perineum and around the anus and may develop into soft warty vegetating lesions, but remain relatively asymptomatic. Ulceration is rare. Diagnosis is by biopsy which shows eosinophilic infiltration (there may be a blood eosinophilia) or frank giant cell granuloma formation around viable and calcified *S. haematobium* ova with a characteristic terminal spine. Other granulomatous conditions, especially tuberculosis, may be suspected. Ova may be recovered from urine or stool. Treatment of choice for *S. haematobium* is praziquantel.

## Amyloid

The non-tender, smooth, yellowish, waxy, occasionally hemorrhagic papules that constitute the most common cutaneous lesion of primary systemic amyloidosis have predilection for the anogenital region, as well as the face. Amyloidosis focalized to the penis is very rare (six cases).<sup>45,46</sup> Primary amyloid of the urethra is very rare but accurate diagnosis is essential as it presents like penile carcinoma with dysuria, bloody discharge, and tender induration of the penis.

## Syringoma

Syringoma is a common benign tumor of eccrine sweat glands usually occurring as multiple symmetrical flesh-colored papules around the eyelids. Rarely, there may be a more widespread distribution. Some cases of multiple syringoma focalized to the penis have been described.<sup>47</sup>

## Non-venereal Sclerosing Lymphangitis/ Penile Venereal edema

Non-venereal sclerosing lymphangitis/penile venereal edema/Mondor phlebitis/localized penile lymphedema/penile lymphocele has become increasingly recognized in recent times and probably went unrecorded previously.<sup>1,2,48–50</sup> Patients present with a serpiginous mass in the coronal sulcus spreading sometimes on to the dorsal penis (Fig. 60.27). The lesion may appear for the first time or become tender and enlarge after prolonged or frequent sexual intercourse. The problem usually resolves spontaneously or may rarely require surgical excision.

Fig. 60.27: Non-venereal sclerosing lymphangitis.

## Dermatofibroma

Dermatofibroma or fibrous histiocytoma is a very common benign lesion of skin, but curiously, rather rarely, if ever, found in the anogenital area. It is thought to represent aberrant healing following an insect bite. One penile case appears in the literature in an 8-year-old boy.<sup>51</sup>

## Epidermoid and Pilar Cysts

These lesions are probably much more common than the literature attests. Giant or unusual lesions only attract attention.<sup>52</sup>

## Scrotal Calcinosis

Scrotal calcinosis is a relatively common, benign idiopathic disorder presenting as rock hard, smooth white papules or nodules on the scrotum (Fig. 60.28). It is much rarer on the vulva. Occasionally, they may become secondarily inflamed or infected following trauma. In endemic areas of onchocerciasis, like West Africa, calcified scrotal cysts may be due to the living or dead nematodes of *Onchocerca volvulus*. Patients usually have evidence of the disease elsewhere.<sup>53</sup> Treatment is surgical but recurrence is frequent.

## Verruciform Xanthoma

Verruciform xanthoma is a rare entity and presents as a painless, yellow-brown or red, verrucous, sessile or papillary plaque. It has a predilection for the oral mucosa but cases affecting the anogenital region have been described.<sup>54</sup> Treatment is by surgical excision.

Fig. 60.28: Nodules of scrotal calcinosis.

## Langerhans Cell Histiocytosis

Solitary to multiple, pruritic, yellowish-red brown papules or nodules, with central foci of ulceration, sometimes in clusters, with crust or scale, involving the perineum or inguinal regions but also other skin folds and non-intertriginous sites in a child, or occasionally an adult should arouse the suspicion of Langerhans cell histiocytosis.<sup>55,56</sup> Primary penile ulceration has been reported as a presentation.<sup>55</sup> Full assessment should be undertaken to exclude systemic disease, which manifests as exophthalmos, lymphadenopathy, hepatosplenomegaly, and polyuria.

## Foreign Body

Oil, silicon, plastic or glass beads, small smooth stones may be introduced into the skin of the penis and cause clinical and radiographic confusion. These can elicit a paraffinoma, silicone granuloma or sclerosing lipogranuloma.<sup>1,2</sup> In the Philippines, the practice is called “bullectus,” in Sumatra “persimbraon” and in Korea “chagan ball.” In Thailand, it is called “muksha,” or “tanchu” after a Japanese hair pomade whose glass container is melted down and fashioned into glass balls that are then inserted subcutaneously in the penile shaft. The insertion of real pearls has been reported—papular pearly penile pearls. These practices are believed to have started in the far east after the second world war. Rarely, an insect may enter the urethra and be visible through the external urethral meatus (Fig. 60.29).

## Penile Horn

Cutaneous horns (Fig. 60.30) are a type of verrucous lesion marked by excessive and increasing keratosis.<sup>47</sup> Only a few cases of penile

**Fig. 60.29:** Insect with its egg in the penile urethra. Courtesy: Dinesh Govil, Jhansi, India.

**Fig. 60.30:** Penile cutaneous horn with underlying squamous cell carcinoma. Courtesy: Amrinder J Kanwar, Chandigarh, India.

horn have been reported. The hyperkeratosis of the cutaneous horn may eventuate from numerous dermatological lesions including burns, naevi, angiomas, Bowen disease, condyloma acuminata, actinic keratoses, seborrheic keratoses/basal cell papillomas, basal cell carcinoma, verrucous carcinoma, and squamous carcinoma. Chronic inflammation and recent circumcision for long-standing phimosis are important predisposing factors. The lesion is premalignant or, in one-third of cases, malignant at presentation with squamous cell carcinoma being the underlying pathology. Treatment should be by adequate excision and follow-up because recurrence may occur.

## Basal Cell Carcinoma

Basal cell carcinoma is a locally invasive neoplasm of the pilosebaceous apparatus. Although the most common type of skin cancer, it is rare in the anogenital area because sun exposure is more important as an etiological factor than biological age. It presents as an indolent nodule or ulcer with a pearly edge: occasionally it is pigmented or flat and morphoeic. Basal cell carcinoma very very rarely and metastasizes multiple erosive scrotal basal cell carcinomas and are associated with this risk. It can be a straight-forward clinical diagnosis elsewhere on the body, but less easy around the genitalia where it may not be suspected because of its rarity.<sup>57</sup> Surgical excision is the treatment of choice.

## Porokeratosis

Genital porokeratosis of Mibelli is rare.<sup>58</sup> Annular raised, double-rimmed lesions have been found in the natal cleft and on the penis and scrotum. They may be misdiagnosed clinically as granuloma annulare or lichen planus but biopsy through the edge shows the characteristic coronoid lamella histologically.

## Pseudoepitheliomatous, Micaceous, and Keratotic Balanitis (PEMKB)

Pseudoepitheliomatous micaceous and keratotic balanitis is a very rare penile condition.<sup>1,2,15</sup> It presents as thick, scaly, micaceous

patches on the glans penis from which a verrucous or erosive tumor may emerge. It occurs in older men who have not been circumcised. It has been misdiagnosed as Reiter disease. PEMKB is probably a form of lichen sclerosus-related locally invasive verrucous carcinoma.

Metastases have not been reported except in association with penile cutaneous horns. Treatment can pose a difficult problem with recurrence and chronicity being common. Topical 5-fluorouracil (5-FU), radiotherapy, and surgery have all been suggested.

### Penile Carcinoma in Situ (PCIS)

Erythroplasia of Queyrat (EQ) and Bowen disease (BD) of the penis (Fig. 60.31) describe carcinoma *in situ* of the penis (PCIS).<sup>1,2,59–61</sup> They are synonymous in this respect, although BD is used to refer to squamous cell carcinoma *in situ* at other cutaneous sites. EQ should be used as a term for red, shiny patches or plaques of the mucosal sites, glans and prepuce of the uncircumcised, and BD for red scaly patches and plaques of the keratinized sites. Bowenoid papulosis (BP) is an analogous, but distinct, entity and presents as multiple small flat topped, often pigmented pink or skin colored papules coalescing to form plaques (Fig. 60.32). It usually occurs in young, sexually active circumcised men, primarily

on the penile shaft but can also occur on the glans, prepuce, and frenulum. BP is associated with multiple HPV subtypes, including benign subtypes (6 or 11) and the oncogenic subtypes 16, 18 and 33. Penile intraepithelial neoplasia (PIN—corresponding to CIN, VIN, and AIN) is an increasingly encountered term, and is used here as a clinical umbrella, but there is as yet no formal consensus on clinicopathological classification and clinical utility.<sup>62</sup> All describe disorders of the penis in uncircumcised, predominantly Caucasian men. Circumcised patients with PCIS have been recorded. Some patients may be quite young. The non-specificity of the clinical appearances makes for an important differential diagnosis which includes inflammatory disorders, such as psoriasis, lichen sclerosus, erosive lichen planus and Zoon balanitis, and cancerous conditions such as Kaposi sarcoma. BP may be mistaken for viral warts, lichen planus, basal cell papilloma, naevi, mollusca, and condylomata lata. A biopsy is indicated in most instances. The histology is of squamous carcinoma *in situ*. (Fig. 60.33) Treatment depends on many factors. It should begin with circumcision. At a stroke, this removes a major risk factor for cancer, provides extensive tissue for histology and an opportunity under anesthesia to examine the whole organ and obtain further biopsies. 5-fluorouracil as a 5% cream is a conventional option for the treatment of BD/EQ/BP. There have been no clinical trials but there have also been no reports of significant local or systemic side effects that save circumlesional irritation. A useful clinical regimen is to use cyclical 5-FU and topical corticosteroid treatment. Other treatments include cryosurgery, curettage and

**Fig. 60.31:** Bowen disease on the background of Lichen Sclerosus.

**Fig. 60.32:** Bowenoid papulosis

**Fig. 60.33:** Intraepithelial neoplasia. Full thickness dysplasia with moderate to marked pleomorphism of the nuclei, increased numbers of mitotic figures which are right in the epidermis, the changes extend down and around a follicle: Bowenoid dysplasia of a high grade. electrocautery, excisional surgery, micrographic surgery, laser, and topical or systemic photodynamic therapy. Patients and their sexual partners presenting with these conditions should be counselled and screened for HPV and other sexually transmitted diseases including HIV infection. Smoking should be discouraged. Follow-up should be long term.

## Squamous Cell Carcinoma

Itch, irritation, pain, bleeding, discharge, ulceration or the discovery of a lump (Fig. 60.34) reveal squamous cell carcinoma.<sup>1,2,62</sup> There is usually a long history of problems with the penis and foreskin amounting to dysuria, dyspareunia, balanoposthitis or phimosis. Irregular nodular and ulcerative morphology is encountered. Background BD/EQ/BP, lichen sclerosus or even lichen planus may be detected. Phimosis should be regarded as a sinister situation and impedes complete inspection and palpation of the glans and coronal sulcus. The presence or absence of inguinal lymphadenopathy should be ascertained, although in penile cancer only 50% of enlarged glands will be found to contain tumor. It is important to establish the presence of other disease states, particularly sexually transmitted diseases and immunocompromise. The differential diagnosis includes the manifestations of PCIS and other erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi sarcoma, Fournier gangrene, pyoderma gangrenosum, and artefact. Genitourinary and urological assessment and biopsy are mandatory. In all patients with suspected squamous cell carcinoma, topical imiquimod histologic confirmation is necessary (Fig. 60.35). Adequate surgical excision is required. This may need to be radical (i.e., penile amputation) depending on location and extent.

**Fig. 60.34:** Squamous cell carcinoma of the penis.

**Fig. 60.35:** Invasive squamous carcinoma. The surface shows hyperkeratosis and acanthosis. Deep to that there is chronic inflammation and extensive infiltration of the underlying tissue by islands of moderately differentiated squamous carcinoma. Reproduced with permission from: male anogenital skin diseases, Ref.2.

Lymphatic or hematogenous dissemination requires individualized multidisciplinary management. The prognosis is poor. Recurrence and progressive malignant transformation does occur. The options of Mohs' micrographic surgery, laser destruction, and adjuvant interferon alpha 2b should be considered. The precise etiology of the types of PIN, verrucous carcinoma, and frank invasive squamous cell carcinoma of the penis is unknown. The natural history of EQ/BD would be consistent with a local carcinogenic influence in uncircumcised men. Smegma has been proposed as that factor with additional contributions from poor hygiene, trauma, friction, heat, maceration, and inflammation. Quantifying the malignant potential of BD/EQ/BP/PCIS is not easy, but they are acknowledged risks for penile cancer. The presence of a foreskin confers cancer risk. Circumcision appears to protect against penile carcinoma unless the circumcision was performed for penile disease. But cases of malignancy in those circumcised at birth have occurred. Carcinoma of the penis accounts for less than 1% of deaths from cancer in the USA but constitutes 10–20% of tumors seen in males in either underdeveloped countries or in areas where early circumcision is not routinely practised. Phimosis and balanitis are known risk factors for penile cancer. Poor personal and sexual hygiene and phimosis may lead to the retention of smegma and balanitis. Also it has not been widely appreciated that phimosis is a physical sign and not a diagnosis. There may be more in the carcinogenic propensity of phimosis than simply physical retention of smegma. Lichen sclerosus, a common cause of phimosis in men, is a premalignant

condition predisposing to penile carcinoma. Chronic erosive and hypertrophic lichen planus are also premalignant conditions and can cause phimosis. Smoking is a risk factor independent of phimosis for penile carcinoma and is also a recognized risk factor for cervical cancer. Smoking may cause squamoepithelial cancer not only in parts of the body in contact with smoke, but also at distant sites by dissemination of carcinogens in the circulation or in secretions. Penis cancer has been reported to complicate renal transplantation, PUVA (psoralen ultraviolet A), photochemotherapy, and possibly other treatments for psoriasis. The risk of penis cancer is five to six fold increased in HIV infection. Although penile carcinoma is associated with multiple sexual partners and previous sexually transmitted disease, the epidemiological features are not those characteristic of a sexually transmitted disease—unlike carcinoma of the cervix and to a lesser extent anal carcinoma, where the evidence is for STD with HPV as the etiological agent. Yet penile cancer puts wives and partners at risk of cervical cancer. There is a high prevalence in sexual partners of women with cervical intraepithelial neoplasia (CIN), and PCIS can be found in men being screened for infection. HPV may be found in the lesions of EQ/BD/BP (Types 8, 16, 18, 31, 42) and in 15–80% of penile cancers (Types 16, 18, 31, 33, 35), but there are exceptions. It has been suggested that EQ may be defined by co-infection with HPV type 8 and other carcinogenic HPV types.<sup>63</sup>

### Verrucous Carcinoma/Buschke Löwenstein Tumor (BLT)/Giant Condyloma

Verrucous carcinoma<sup>1,2</sup> is a rare, low-grade, well-differentiated squamous carcinoma. It is a dramatic clinical lesion, often polypoid or cauliflower like. Although, locally deeply invasive, it is well-demarcated from surrounding tissue and probably does not metastasize. Suspected verrucous carcinoma demands a deep surgical biopsy. Frank squamous carcinoma and foci of invasive squamous carcinoma have been reported in some cases of anogenital verrucous carcinoma. A specific etiology for verrucous carcinoma/BLT has not been identified, but an apparent origin from common genital warts is thought likely. BLT is firmly associated with low risk HPV types 6 and/or 11. A relationship with lichen sclerosus has also been observed.

### Malignant Melanoma

Malignant melanoma of the penis is a very rare condition. There are less than 100 cases in the literature.<sup>1,2,64</sup> It is estimated to account for 1–1.5% of all malignancies of the penis and less than 0.15% of all melanomas. Melanoma is even rarer on the scrotum with only four cases appearing in the literature. Vulval melanoma is commoner. Melanoma presents as pigmented macules or as a pigmented or amelanotic papule or nodule (possibly developing from a lentiginous area or pre-existing dysplastic naevus), which may ulcerate or bleed. Patients are usually middle aged or older, although it has been reported in a boy. It is exceedingly rare in Asians and has not been reported

in blacks. Melanoma of the urethra has been described.<sup>65</sup> Sixty to seventy percent of the lesions occur on the glans. There may be a family history of melanoma and other atypical or “dysplastic” naevi on examination. Forty to fifty per cent of patients have lymphatic or other metastatic dissemination at the time of presentation. Treatment is by primary excision. Subsequent management depends on the Breslow thickness of the lesion and complete clinical staging. Radical surgery and chemotherapy may be needed, but the prognosis is poor for all melanomas that have already metastasized.

### Extramammary Paget Disease

Extramammary Paget disease presents as an irritating, itchy, burning, red scaly patch, patches or plaques. Paget disease can be found anywhere around the anogenital area, including the glans penis and may be multicentric. It is frequently misdiagnosed as an inflammatory dermatosis, such as psoriasis. A biopsy is mandatory. The disease behaves indolently, spreading by local extension and metastasis.<sup>1,2</sup> Mammary Paget disease is an epidermal manifestation of an underlying breast adenocarcinoma. Extramammary Paget disease is found in areas rich in apocrine sweat glands, such as the axillae and anogenital region. It can be associated with an underlying malignancy. While considered to represent a form of carcinoma *in situ*, it may, itself, become invasive and there may be subjacent carcinoma, for example in periurethral glands or more distant cancer of the prostate or bladder. Co-existent genital and extragenital Paget disease is extremely rare. Paget disease has been treated with cryotherapy and topical 5—fluorouracil. Widespread excisional surgery like Mohs’ and plastic repair (if needed) is probably the treatment of choice. Topical imiquimod shows promise in obviating or limiting the extent of surgery.<sup>61</sup> Radiotherapy is regarded as ineffective. Photodynamic therapy may be useful.

### Mycosis Fungoides

Mycosis fungoides is a cutaneous T-cell lymphoma. It can be difficult to diagnose clinically and histologically and runs a long, indolent, and variable course. Fixed, red, scaly eczematoid or psoriasiform patches and plaques are the early signs. These may be easily diagnosed as due to one or other benign inflammatory dermatosis and respond partially and intermittently to topical corticosteroid treatment. Localized anogenital disease has been described.<sup>66,67</sup>

### Kaposi Sarcoma

Genital KS is an important entity.<sup>1,2,68</sup> Solitary KS of the penis was recognized, if rarely, before the HIV epidemic. In patients with HIV infection, KS can occur as a dull red patch or plaque on the glans penis or preputial sac, as well as one of its more classical manifestations, namely purple, slightly scaly patches or plaques, nodules, or ulcerative lesions. An engorged, “hypervascular” presentation has been reported, as has been phimosis. KS is common in homosexuality associated

**Table 60.10:** Treatment Options for Kaposi Sarcoma

Local	Systemic
Cryotherapy	Aggressive chemotherapy
Radiotherapy	Liposomal doxorubicin
Intralesional, e.g., TNF $\alpha$ , IFN $\gamma$	Isotretinoin
Vinca alkaloids	
Surgery	
Cosmetic camouflage	

HIV, but less so in intravenous drug abusers and hemophiliacs. Classical KS occurs in elderly male central Europeans, Italians or Jews, and is solitary and acral. Endemic KS occurs in black Africans and is florid and aggressive. A third group of KS occurs in patients with iatrogenic immunosuppression. AIDS-related KS is multicentric and often involves the face, oral mucosa, palate, and genitalia. The characteristic lesion is a purple nodule, which may ulcerate. The differential diagnosis includes naevi, angioma, angiokeratoma, and histiocytoma, but cryptococcosis, histoplasmosis, leishmaniasis, pneumocystis, and dermatophytosis may also mimic and/or complicate KS. KS masquerading as pyogenic granuloma has become a well-recognized clinical presentation, as has bacillary angiomatosis masquerading as KS. KS is now known to be due to human herpes virus 8. There is no cure for KS but lesions may involute with highly active antiretroviral therapy (HAART). Radiotherapy, local and systemic chemotherapy, liposomal doxorubicin have their places in management (Table 60.10).

## Penile Metastases

Metastases to the penis are rare, but several hundred cases have been reported.<sup>69</sup> They are usually secondary to cancer of the urogenital tract (e.g., bladder or prostate) or gastrointestinal system (e.g., rectum). They may present with pain, swelling, priapism, urinary symptoms, or hematuria. A cutaneous nodule or nodules may be seen or infiltration of the deeper penile structures palpated.

# 61

## Introduction

Vulvar dermatoses are the non-neoplastic, non-venereal epithelial disorders of the labia minora, labia majora, and vaginal introitus. Both keratinized skin and mucocutaneous surfaces may be affected. Such dermatoses may begin insidiously, be present for a long time without subjective symptoms, or declare themselves in the form of intractable itch, which may lead to severe discomfort. In addition, they may be a heralding sign to systemic autoimmune disorders or vulvar malignancy. Thus, being able to recognize and treat the vulvar dermatoses is not only vital for comfort but also for the overall health of the patient. This chapter will herald the most prevalent dermatoses affecting external genitalia in women.

## Taking History

Due to the sensitive nature of complaints related to the vulva, practitioners must take time to determine the extent of the disease, otherwise suboptimal treatment may result. The physician should investigate the onset and duration of the problem as well as the specific location, any aggravating or alleviating factors, and the character of the symptoms (itching vs. pain). In particular, one should determine whether the problem is affecting micturition, defecation, or sexual functioning. One should ask about current sexual practices, history of sexually transmitted diseases, and any history of genital surgeries such as labiaplasty. Past medical history, family history, medications, especially any topical preparations or over-the-counter products applied to the vulva, and allergies may be relevant to vulvar problems as well.

## Physical Examination of the Vulva

The examination should be undertaken using proper lighting with the patient placed in the dorsal lithotomy position. One may also want to keep a mirror on hand in case the patient would like to identify areas of concern. A camera may be useful for documenting a baseline physical examination. First, one should examine the external vulva for any growths, erythema, ulcerations, erosions, atrophy, lichenification, or tenderness. Then,

examine the internal vulva, making note of any adhesions and architectural abnormalities, including phimosis of the clitoris and narrowing of the introitus. One may apply a sterile cotton swab to the vestibule of the vulva to determine tenderness. For better view of the vagina, one may utilize a speculum. Culture swabs may also be taken if there is a suspicion of infection at the time of examination.

If the physical examination reveals atypical lesions or abnormal epithelial tissue in the vulva, a biopsy may be undertaken to confirm the diagnosis.

## Differential Diagnosis

For the purposes of this chapter, we will focus on the most common vulvar dermatoses such as papulosquamous and bullous diseases. Primary and secondary skin lesions on genitalia may include patches, papules and plaques, vesicles, erosions, and scarring. While evaluating the patient with vulvar problems, the clinician should generate a broad differential diagnosis based on the morphology of presenting lesions (Table 61.1). Within each of those categories, the clinician ought to consider a wider list of inflammatory processes, infections, and malignancies. While some infections, such as herpes simplex are more common, relatively rare infections may also been seen, particularly in the HIV positive population, including histoplasmosis, cryptococcus, coccidiomycosis, blastomycosis, molluscum contagiosum, and cutaneous tuberculosis. The HIV positive patients are also more likely to show signs of premalignant or malignant conditions such as florid condyloma accuminata, squamous cell carcinoma, and Kaposi sarcoma. The clinician will then use objective data gathered from physical examination, laboratory workup, and biopsy to settle on a diagnosis.

## Lichen Sclerosus

Lichen sclerosus (LS) is a chronic inflammatory and potentially scarring disorder of the vulva and the perianal region and sometimes the other extragenital sites. In the male counterpart, penile involvement is quite common. Originally described by Hallopeau

**Table 61.1:** Nonvenereal Vulvar Dermatoses

Papules	Inflammatory dermatoses
Angiokeratoma	Lichen sclerosus
Acrochordon	Lichen planus
Fox–Fordyce disease	Psoriasis
Seborrheic keratosis	Lichen simplex chronicus
Vestibular papillomatosis	Discoid lupus erythematosus
Cherry angioma	Tinea
Folliculitis	Erythrasma
Syringomas	Seborrheic dermatitis
Hemangioma	Allergic contact dermatitis
	Irritant contact dermatitis
	Radiodermatitis
Vulvar lesions in systemic disease	Pigmentary alterations
Inflammatory bowel disease	Vitiligo
Systemic lupus erythematosus	Lentigenes (including
Acrodermatitis enteropathica	genodermatoses with
Glucagonoma syndrome (Necrolytic migratory erythema)	genital mucosal lentigenes such as Laugier–Hunziker syndrome)
Ulcers and erosive diseases	Cysts/nodules
Erosive lichen planus	Epidermoid cyst
Lichen sclerosus	Bartholin cyst
Pemphigus vulgaris	Mucinous cyst
Cicatricial pemphigoid	Hidradenomas
Hailey–Hailey disease	Hidradenitis suppurativa
Epidermolysis bullosa aquisita	Endometriosis
Linear IgA disease	
Toxic epidermal necrolysis

in 1889, the vulvar form primarily affects postmenopausal women and young children, appearing during times of low hormonal output.<sup>1</sup> One study showed an incidence of vulvar LS in 1.7% of patients presenting to a general gynecology practice.<sup>2</sup> The disease may be associated with systemic autoimmune disorders as well as vulvar malignancy with disease progression. A study of 190 women with LS showed 28% to have one or more autoimmune disorders, over half of them with thyroid disease; other prevalent disorders included alopecia areata, pernicious anemia, and morphea.<sup>3</sup> A retrospective review of 202 patients with LS showed that

17% had extragenital psoriasis on examination, compared with 2–3% in the general population.<sup>4</sup> Etiology is unknown, but basic research suggests that genetic predisposition to autoimmunity, chronic infections, mechanical forces of friction or rubbing, and specific autoimmunity to elements of the extracellular matrix and basement membrane zone may all play a role.<sup>5–7</sup>

## CLINICAL PRESENTATION

Patients generally present with complaints of pruritus, soreness, or dyspareunia, although they may also remain asymptomatic. Young females with the disease may mention urinary or bowel symptoms. Clinicians should also investigate a history of thyroid or other autoimmune disorders in the family.

The physical examination classically shows vulvar hypopigmentation and thin, wrinkled and atrophic skin, often in a figure-of-eight distribution around the vulva and the anus. There may be hyperkeratotic as well as eroded areas of the vulva. Fissures and erosions present in the perineal area may be responsible for pain during defecation, and the hesitancy to defecate may lead to symptoms suggestive of constipation.<sup>8</sup> Young girls may also present with an infantile perineal protrusion, a pyramidal soft tissue swelling along the median perineal raphe.<sup>9</sup> Early on in the disease, the vulva may appear whitened and edematous with possible resorption of the labia while later in the disease the labia demonstrate more of a wrinkled “cigarette paper” appearance. (Fig. 61.1)

The thinned skin may also demonstrate ecchymosis, telangiectasias, hemorrhagic blisters, or purpura, the latter of which is more often seen in young girls.<sup>10</sup> External genitalia may exhibit structural changes due to scarring. One may see burying

**Fig. 61.1:** Lichen sclerosus. Courtesy: Andrew Goldstein, MD.

of the clitoris under the clitoral hood, fusion of the labia minora to the labia majora, or more extensive midline fusion. In severe disease, the complete loss of labia minora may result in narrowing of the introitus. These features of the late disease may lead to the clinical diagnosis. If the disease has progressed without medical monitoring, a patient might present with a squamous cell carcinoma arising within the vulvar LS. Extragenital LS is seen in 15–20% of patients with genital LS, particularly in the submammary region, the shoulders, neck, and wrists, presenting as asymptomatic or slightly itching white wrinkled patches of skin showing small pigmented lesions or hyperkeratotic plugs in relation to follicles.

## DIAGNOSIS

Early LS may appear similar to many papulosquamous eruptions or dermatitis; however, more advanced disease may be confused with other scarring disorders, including erosive lichen planus, mucous membrane pemphigoid, and morphea. To rule out these disorders, laboratory and pathologic investigations are often indicated. Given the strong association with autoimmune disorders, one may consider checking hemogram, vitamin B12, TSH, and blood glucose. As eroded vulvar skin may increase the predisposition for infection, bacterial and viral culture may be helpful.<sup>8</sup> A skin biopsy taken from the edge of a lesion will establish the diagnosis definitively and is particularly indicated if any growths noted within the vulvar LS. The histology classically demonstrates compact orthokeratosis, follicular plugging (nonmucosal sites), a thinned epidermis, vacuolization of the basal layer, and hyalinization of the papillary dermis. A thick lichenoid lymphocytic infiltrate may be seen. Squamous hyperplasia is not uncommon (Fig. 61.2).

If there is erosion, direct immunofluorescence (DIF) would help to differentiate LS from mucous membrane pemphigoid. The DIF will be negative in LS. Biopsy is less practical in very young females as it may require general anesthesia.<sup>11</sup>

## TREATMENT

Disease control is a key to remission and prevention of malignant transformation in LS. Ultrapotent topical corticosteroids are the standard treatment for vulvar LS. Efficacy in controlled trials has been demonstrated for clobetasol propionate 0.05% ointment. Initial therapy with clobetasol ointment 0.05% includes once daily application for 3 months, followed by once to twice weekly application as needed for maintenance.<sup>8</sup> Often patients have improvement in symptoms within weeks, including decrease in erythema if scarring has not yet occurred.<sup>10</sup> The risks of chronic clobetasol use include skin thinning and telangiectasia and must be weighed against the benefits of prevention of scarring, especially in small children. A retrospective chart review of 129 women with LS demonstrated that after induction of remission with super potent topical corticosteroid, 98% of the patients were maintained on remission using low-to-moderate potency topical corticosteroids titrated to treat symptoms.<sup>12</sup> Second-line treatments include the topical calcineurin inhibitors, which have shown efficacy and safety in a clinical trial, with 43% of patients achieving disease clearance after 16 weeks of twice daily treatment with tacrolimus ointment 0.1%.<sup>13,14</sup>

Surgical correction may be appropriate when LS has caused severe distortion of vulvar architecture.<sup>15</sup> In particular, a Fenton procedure may be performed to alleviate painful splitting of the posterior forchette.<sup>16</sup> Topical testosterone has been used and shown to cause virilization, therefore, is not recommended. One may also recommend use of soap-free cleansers and fragrance-free emollients to reduce any irritation and sensitization of the skin and mucous membranes. If there is an indication, one should treat any concomitant infections in the genital area with appropriate antibiotics and antifungals. Patients should be recommended to use adequate lubrication during sexual intercourse, and in cases of severe associated sexual dysfunction, support groups or sexual counseling may be of benefit.<sup>8</sup> Both patients and clinicians must engage in lifelong monitoring and follow-up for disease progression and potential development of malignancies.

## Lichen Planus

Lichen planus (LP) is an inflammatory, autoimmune vulvar disease which is often part of a more extensive disease of the skin and mucous membranes. While nonmucosal LP is more self-limited condition, vulvar LP is often longer-lasting and affects both keratinized and mucosal surfaces of the genitalia. The disorder was first described in 1867 by Erasmus Wilson.<sup>17</sup> Most patients with vulvar LP are women in the 6<sup>th</sup> decade of life.<sup>5</sup> Genital disease can take four clinical variants: genital disease in the setting of cutaneous disease, hypertrophic disease, erosive disease, and lichen planopilaris. Erosive LP may cause extensive disease of the vulva, the vagina, and the oral mucosa, and was first recognized in 1980s by Pelisse, who coined the name “vulvovaginal-gingival syndrome.” Though the cause of LP is unknown, the accepted theory is that activated T cells begin attacking basal keratinocytes.<sup>5</sup> Unlike solely cutaneous LP,

erosive vulvar LP has been associated with autoimmune disorders, particularly thyroid disease, as well as antinuclear (25%) and antithyroid (19%) antibodies.<sup>3</sup> In addition, the vulvovaginal-gingival syndrome has been associated with HLA-DQB1\*0201 allele.<sup>18</sup>

## CLINICAL PRESENTATION

Patients with vulvar LP often present vulvar or vaginal discharge, intense pain, itching, burning, dyspareunia, and postcoital bleeding. Patients may demonstrate distress and anxiety over the problem, particularly as it relates to sexual functioning.<sup>2</sup> A cohort of 42 Italian women with histologically confirmed oral LP demonstrated a 57% prevalence rate of vulvar LP.<sup>19</sup> Thus, there is significant disease overlap between different clinical forms of LP.

Similar to cutaneous LP, vulvar disease may present with classic violaceous flat-topped papules and plaques on the labia majora, labia minora, or the mons pubis in a symmetric fashion. Patients with erosive LP usually present with glassy, brightly erythematous erosions associated with Wickham striae noted in the form of peripheral whitening (Fig. 61.3).

In a study of 161 vulvar LP patients, 74% had erosions, 66% had red/purple color, 63% had scarring, and 56% had reticulated lesions.<sup>3</sup> In the hypertrophic disease, hyperkeratotic white plaques are usually limited to the perineum and may resemble squamous cell carcinoma. Erosive LP, often part of the vulvovaginal-gingival syndrome, consists of superficial violaceous erosions that may be lined by white glassy reticulated papules and plaques, extending into the vaginal vestibule in 70% of cases.<sup>5</sup> A study of 58 women with erosive LP in Norway showed vaginal synechiae in 29 women and total obliteration of the vagina in 9 women.<sup>20</sup> Extensive disease may lead to adhesions and distortion of vulvar architecture, which

may obliterate the vaginal canal, causing difficulty with speculum examination or sexual intercourse.<sup>5</sup> One may also see discharge or contact bleeding on physical examination. If erosive LP is suspected, one should investigate the gingival mucosa for signs of white, lacy reticulations, which may also be seen on buccal mucosa and tongue in classic LP.<sup>17,21</sup> Lichen planopilaris consists of scarring hair loss with perifollicular scale and erythema and may be seen in conjunction with vulvar LP.

## DIAGNOSIS

Vulvar LP has been associated with autoimmune diseases; thus, one might consider checking hemogram, vitamin B<sub>12</sub>, TSH, and blood glucose. There is a general consensus to check viral hepatitis serologies only in cutaneous form of LP.<sup>22</sup> If one suspects fungal or bacterial superinfection, cultures should be taken and appropriate treatment undertaken. LP is most commonly misdiagnosed as LS. However, the vaginal involvement is more typical for LP, contrary to more atrophic, “cigarette paper”-like patches of LS. Other disorders in the differential diagnosis of LP include immunobullous diseases, such as mucous membrane pemphigoid, pemphigus vulgaris, and linear IgA bullous diseases, since they may present with erosions. However, contrary to the immunobullous diseases, the vulvar LP will rarely present with bullae or vesicles.<sup>2</sup> If the patient’s history supports recent exposure to beta-blockers, methyldopa, penicillamine, quinidine, NSAIDs, sulfonyleurea agents, carbamazepine, lithium, allopurinol, and tetracyclines, one might consider lichenoid drug reaction and erythema multiforme in differential diagnosis.<sup>2</sup>

When clinical differential diagnosis is broad and the patient consents to a biopsy, a punch biopsy with direct immunofluorescence is recommended for definitive diagnosis. One should biopsy the border of an eroded area.<sup>5</sup> The typical histology shows irregular epidermal acanthosis, hypergranulosis, some liquefaction degeneration of the basal layer, and a lichenoid infiltrate of lymphocytes. Degenerating keratinocytes, known as colloid bodies, may also be seen near the dermal-epidermal junction.<sup>17</sup> Basal keratinocyte changes in vulvar LP may be mistaken for vulvar intraepithelial neoplasia (VIN), which can lead to a diagnostic pitfall and unnecessary surgery.<sup>1</sup> In erosive disease, the stratum corneum may be lost. In hypertrophic disease, one will see hyperkeratosis along with acanthosis. The DIF will exclude disorders like pemphigus vulgaris (Fig. 61.4).

## TREATMENT

Corticosteroid ointments are typically the mainstay of treatment for vulvar LP. Ultra potent steroids like clobetasol propionate 0.05% should be used daily until all active lesions have resolved.<sup>2</sup> Ointments are preferable to creams.<sup>17</sup> A study of 114 women with erosive vulvar LP showed that 71% improved with corticosteroid treatment; some patients also benefited from combined therapy of corticosteroids with antimicrobials or antifungal treatments.<sup>23</sup> When vaginal disease is present, 25 mg hydrocortisone suppositories twice daily may be used

**Fig. 61.3:** Vulvar lichen planus. *Courtesy: Andrew Goldstein, MD.*

**Fig. 61.4:** Histopathology in lichen planus. *Courtesy: Andrew Goldstein, MD.*

to alleviate symptoms.<sup>17</sup> Multiple studies have demonstrated success in treating disease with topical calcineurin inhibitors such as tacrolimus.<sup>13</sup> With more extensive disease, systemic immunomodulators have been attempted in small-case numbers. Prednisone beginning at 40–60 mg daily for 2–4 weeks is a reasonable start point.<sup>13</sup> Other medications which have been used in small studies include hydroxychloroquine, oral retinoids, methotrexate, cyclophosphamide, and mycophenolate mofetil.<sup>13,24</sup> One case report documented improvement of vulvar as well as oral and cutaneous LP with adalimumab within 6 weeks and almost full resolution after week 22.<sup>25</sup> Another report documented a response of extensive erosive oral and genital LP to cyclosporine at 300 mg daily within 6 weeks.<sup>26</sup> Just as with vulvar LS, surgical intervention may have its role when significant architectural distortion has happened.<sup>2,27</sup> Experienced clinicians have had some success in symptom control with lidocaine gel, oral analgesics, and low-dose antidepressant therapy at night time.<sup>16</sup>

## Dermatitis and Lichen Simplex Chronicus

Vulvar dermatitis is a commonly seen pathology, seen in 20–30% of patients in a vulvar clinic.<sup>28</sup> The disorder may be a manifestation of endogenous dermatitis such as atopic dermatitis or seborrheic dermatitis, exogenous dermatitis including allergic contact or irritant contact dermatitis, or the more chronic form known as lichen simplex chronicus (LSC), caused by persistent itching and scratching.<sup>5</sup> Furthermore, anxiety and depression may play a role in worsening the itch-scratch cycle to perpetuate these types of dermatoses.<sup>29,30</sup> LSC may not only be caused by dermatitis, but may also be the result of chronic candidiasis, psoriasis, LS, parasite infection, or neoplasia.<sup>5</sup> In a study of 38 patients with vulvar dermatitis, 97% had underlying atopic dermatitis or seborrheic dermatitis,<sup>28</sup> thus it is believed that an endogenous predisposition occurs in most patients.

### Clinical Presentation

Patients give a history of vulvar pruritus, soreness, and often dyspareunia. Patients with LSC in particular may experience unconscious scratching while sleeping, called the Penelope

phenomenon.<sup>5,29</sup> Given the prevalence of underlying atopy in this group, a clinician should acquire a history of allergies, asthma, or eczema. Thorough questioning may also reveal a history of contact allergies to substances commonly applied to the vulva. It is prudent to ask about possible skin irritation from sweat or urine, particularly in the elderly women. Excess moisture on perineal skin along with urine can significantly increase the pH of the skin, deteriorating the acid mantle which protects from infection and irritation.<sup>31</sup> One should specifically ask about vaginal itching and discharge since trichomoniasis and candidiasis are prevalent disorders that could lead to vulvar symptoms.<sup>32</sup>

The clinical presentation may range from acute bright erythema with crusting and excoriations to more chronic form of LSC, characterized by gray or brown-pink labia majora with cobblestone pattern, loss of hair and lichenification (Fig. 61.5).

LSC may also lead to hypo- or hyper-pigmentation of affected skin.<sup>5</sup> To confirm the suspicion of underlying atopy, one should examine patient's entire body for patches of eczema, Dennie–Morgan folds under the eyelids (usually seen in children in acute/subacute presentation), or hand dermatitis. In patients with seborrheic dermatitis, there may be orange-pink patches and thin plaques with fine scale on the mons pubis, labia majora, and the intertriginous area.<sup>31</sup> In addition, there may be greasy yellow scales along the nasolabial folds and within the eyebrows.

### DIAGNOSIS

Usually the physical examination along with the history will lead to a diagnosis of vulvar dermatitis or more specifically to an appropriate subtype of dermatitis, such as atopic dermatitis, allergic contact dermatitis, irritant contact dermatitis, or LSC. The differential diagnosis may include psoriasis and extramammary Paget disease, but both will have more well-demarcated plaques

**Fig. 61.5:** Lichen simplex chronicus. *Courtesy: Andrew Goldstein, MD.*

and can be ruled out by skin biopsy. One should take a fungal and/or bacterial culture of the region if infection is suspected, as candida and group B streptococcus are not unusual. Scraping for scabies may be helpful.<sup>30,33</sup> Early LS may also present similar to vulvar dermatitis; however, the clinical presentation will evolve and exhibit the characteristic appearance of the disease.

A laboratory workup is usually only performed if other diagnoses are suspected, although one study showed that 20% of patients with vulvar dermatitis had a low serum ferritin, and their symptoms improved with iron supplementation. Thus, checking a serum ferritin may be prudent if history of vegetarianism, blood donation, or previous anemia is given.<sup>28</sup>

If a contact allergen is suggested by the history, patch testing may be performed. Relevant contact allergies were found in 26% of patients with vulvar dermatitis and included fragrances to toiletries, formaldehyde and its releasing preservatives, and Kathon CG, a preservative.<sup>28</sup> Another prospective study of 43 patients with vulvar pruritus revealed 44% prevalence of relevant contact allergies, with the most common allergen being Vagisil (benzocaine, resorcinol, methyl hydroxybenzoate, or sodium sulfite anhydrous).<sup>34</sup> Though contact dermatitis is often suggested by history and physical examination, a biopsy will show spongiosis, acanthosis, parakeratosis, and a dermal inflammatory infiltrate, and in a more chronic condition, one may see hyperkeratosis and hypergranulosis.<sup>35</sup>

## TREATMENT

As with dermatitis seen in other areas of the body, treatment is geared at reducing irritants, reducing inflammation, and improving the skin barrier. If a contact allergen or irritating product is found to be the culprit, the patient must stop the use of that agent. Fragrances should be eliminated from products used to clean or wipe the vulva. If the irritant is urine or sweat, absorbing powders, zinc oxide cream, or absorbing diaper products may reduce exposure. Discontinuing use of tight slacks and undergarments may reduce sweating as well.<sup>35</sup> To reduce inflammation, topical corticosteroids and topical calcineurin-inhibitors (tacrolimus, pimecrolimus) may be used.<sup>5</sup> Open label studies with pimecrolimus have shown efficacy in treating LSC, without the risk of skin thinning as with corticosteroids.<sup>13</sup> In addition, scratching—one of the biggest inducers of inflammation—may be reduced with patient education and palliative measures such as lidocaine gel, sitz baths, and ice pack.<sup>5,35</sup> To improve the skin barrier, emollients such as petrolatum or vegetable oil should be used liberally; this may be particularly important in the post-menopausal and elderly women with significantly increased transepidermal water loss.<sup>36</sup> In addition, some gynecologists prescribe topical estrogen preparations for vulvo-vaginal use in the perimenopausal women, potentially increasing the possibility of endometrial hyperplasia.<sup>36</sup>

To improve the overall discomfort of the patient, antihistamines such as hydroxyzine or diphenhydramine may be used at bedtime.<sup>37</sup> Patients might also benefit from tricyclic antidepressants such as amitriptyline 25 mg at bedtime.<sup>5</sup>

## Psoriasis

Psoriasis is a chronic inflammatory skin disease rarely limited only to the genitals; however, the genital disease is often the most recalcitrant to treatment and can have significant physical and psychological impact on the patient. Often the practitioner must specifically ask the patient with psoriasis about lesions on the genitals or that information will not be volunteered. This may be particularly true in the pediatric population, which may present with vulvar psoriasis more often than adults.<sup>38</sup>

## CLINICAL PRESENTATION

The clinician may suspect vulvar psoriasis if the patient has a personal or family history of psoriasis or has a positive review of systems for joint stiffness or pain.<sup>39</sup> Yet, a diagnosis of vulvar psoriasis will most often be made through physical examination. On the mons pubis and the labia majora, one will usually see smooth well-demarcated or sometimes beefy red scaly plaques. However, there is an absence of typical silvery, micaceous scale seen on the trunk or extremities since the vulva is better hydrated than other sites of the body.<sup>31</sup> Only the hair-bearing genital skin is affected by psoriasis, which excludes the labia minora and other mucosal structures. The erythematous plaques may extend toward the perianal and intergluteal cleft region (Fig. 61.6).

One may see other signs of psoriasis on full skin examination, including well-demarcated plaques on the scalp, elbows, knees, or trunk. If the patient has inverse/flexural psoriasis only, the disease may be limited to the genital areas, umbilicus, and axillae.

## DIAGNOSIS

A diagnosis of vulvar psoriasis may be obvious in the case of a patient with a history of psoriasis; however, one may also need to rely on the lesion morphology. If seborrheic dermatitis and psoriasis are seen together in the same patient, one may use the term “sebopsoriasis.” If the lesions are confluent and affect the groin area as well as the labia majora, one might consider tinea cruris, especially if there is festooning border, pustules, or worsening of lesions with use of topical steroids. A potassium

**Fig. 61.6:** Vulvar psoriasis. *Courtesy: Jennifer Powers, MD.*

hydroxide examination of the scraping of the scale should establish the diagnosis.

## TREATMENT

First-line treatment is generally a moderate potency topical corticosteroid, pulsed daily for use when needed and stopped when disease is controlled. However, since corticosteroids may thin the already delicate skin of the groin, topical calcineurin-inhibitors may also be the first-line treatment. Tacrolimus ointment 0.1% has been shown to reduce erythema, desquamation, and infiltration of flexural psoriasis including genital disease.<sup>40</sup> One should treat fungal or candidal superinfection if suspected. Though vulvar psoriasis is typically viewed as a non-scarring process, there have been a few cases described in which biopsy-proven vulvar psoriasis led to scarring of the labia minora as well as sealing of the clitoral hood.<sup>41</sup> This may underscore the importance of treatment, for the disease both in the present and the future.

## Immunobullous Diseases

Acquired autoimmune blistering diseases were associated with tremendous mortality until the development of oral corticosteroids in the 1950s. These disorders, including pemphigus vulgaris (PV), bullous pemphigoid (BP), mucous membrane pemphigoid (MMP), and chronic bullous disease of childhood (CBDC), can affect the female genitalia, though they do not usually affect the vulva exclusively. BP is the most common of these disorders.<sup>31</sup> PV is more commonly seen in people of Ashkenazi Jewish descent with a yearly incidence of 0.1–3.2 cases per 100,000 people.<sup>42</sup> With the exception of CBDC, which is often seen in children, the other disorders affect primarily older adults, particularly the elderly. These disorders share a common pathophysiology in which antibodies bind to building blocks of the epidermis or basement membrane, leading to immune dysfunction and subsequent blister formation. The targets of Immunoglobulin G (IgG) in PV, BP, and MMP are desmoglein 3, BPAG1/2, and BPAG2, respectively.

## CLINICAL PRESENTATION

Patients with immunobullous diseases in their early stages may not present with frank blisters but may have plaques or itching. If the disease is fully developed, then one should note blister locations and whether the bullae are tense or flaccid. If the bullae have been traumatized or are healing, the clinical examination may be positive only for erosions, often crusted. All mucosal sites including eye, mouth, genitals, and anus should be examined for blisters, erosions, and other lesions. If patients have lesions in the mouth, there may be significant decrease in oral intake of foods or liquids. Nikolsky sign, in which upper layers of the skin move laterally with slight pressure, or the Asboe-Hansen sign, in which pressure on an intact bulla moves fluid under nearby and seemingly uninvolved skin, may be seen in these disorders. The diagnosis will be based on a full history and total body-skin examination.

PV will present with flaccid bullae on the skin and oral mucosa, the latter of which is usually the first site of involvement, particularly on the buccal and palatine mucosa.<sup>31</sup> Because these flaccid bullae easily give way to denuded erosions, these patients often complain of significant pain at the site of disease activity. The erosions may be of varying sizes with irregular borders. Vulvar mucosa is infrequently involved, because the antigen desmoglein 3 is found in higher concentration in other sites including the mouth rather than the genital area.<sup>31</sup> In a retrospective review of cases of female genital PV, 38% of patients had vaginal involvement, particularly in the distal one-third of the vagina. If such disease is suspected, one should perform a pelvic examination to determine the extent of involvement.<sup>42</sup>

BP begins with itching and urticarial plaque formation on the trunk, extremities, and flexural sites many months before any blistering begins.<sup>31</sup> When bullae appear, they are tense with erythematous borders and often symmetrical with higher propensity for flexural surfaces. If lesions appear on the vulva, they may become eroded due to frictional forces. Long-standing lesions may be hemorrhagic. In children, lesions may be localized to the vulva.<sup>43</sup> BP may also be associated with an underlying malignancy, so a good review of systems should be taken to evaluate a need for further work up.

MMP, also known as cicatricial pemphigoid is almost always associated with ocular and oral involvement, often presenting with erosive desquamative gingivitis. With early disease, the conjunctivae may be injected, causing pain or a foreign-body sensation; with later disease, scarring of the palpebral conjunctivae to the bulbar conjunctivae may lead to symblepharon formation. The upper aerodigestive tract may also be involved, and skin may be characterized by erythematous plaques or erosions. In MMP with vulvar involvement, patients complain of pain, itching, and dysuria. They may also complain of vision loss, conjunctival injection, and oral discomfort.<sup>31</sup> On physical examination, the labia minora, vaginal vestibule, and introitus may be afflicted with bullae and/or erosions, which may cause architectural distortion with permanent disfigurement.<sup>31</sup> The vulva may appear eroded or with labial fusion in more chronic cases, not unlike erosive LP (Fig. 61.7).

CBDC presents as tense bullae generalized over the body and perioral areas but often also affecting the vulva. The bullae may resemble a “string of pearls” and are marked by an annular, polycyclic appearance and often appear in the flexural areas.

## DIAGNOSIS

One must rule out infectious causes of vesicles and bullae such as HSV infections, particularly when the lesions are limited to the genitals. With vesicular fluid, one may take a viral culture, perform direct fluorescence antibody testing for herpes simplex virus (HSV) 1 and 2, or perform PCR testing for HSV 1 and 2. Lesions of herpes zoster can also occur on the vulva. Bacterial and/or fungal swabs may also be needed to rule out secondary infection as eroded surfaces may easily become colonized with

**Fig. 61.7:** Cicatricial pemphigoid. Courtesy: Andrew Goldstein, MD.

*Staphylococcus aureus*, streptococcus, and candida. If the history is suggestive of unprotected sexual contact or HIV infection, one may also consider Epstein–Barr virus, cytomegalovirus, or syphilis. If erosions, rather than frank vesicles or bullae, are present, then one must also entertain other diagnoses including erosive LP, LS, squamous cell carcinoma, epidermolysis bullosa acquisita, Behcet disease, extramammary Paget disease, or fixed-drug eruption. If bullae and vesicles have been present since childhood, then one might consider inherited forms of bullous disease such as epidermolysis bullosa and Hailey–Hailey disease.

One should perform two skin biopsies—one for H&E staining and one for DIF, the former taken from the lesional skin and the latter taken from peri-lesional skin. On the H&E slide, PV will be characterized by acantholysis above the basal layer of the epidermis along with intraepidermal bullae and may exhibit tombstone phenomenon. DIF will show a “chicken-wire” pattern of fluorescence, highlighting the intraepidermal space surrounding each keratinocyte. BP will be characterized on H&E by a subepidermal bulla filled with eosinophils and neutrophils. DIF will show fine, linear, continuous IgG fluorescence along the basement membrane zone. If salt-split skin is performed, the immune staining will be seen in the roof. MMP will also show subepidermal blister formation on H&E as well as fibrosis in the dermis in older lesions. DIF will show fine linear IgG and/or C3 along the basement membrane zone, and salt-split skin will demonstrate positive staining in the roof. CBDC will be marked by subepidermal vesicles with infiltration of neutrophils. DIF will show linear immunoglobulin A (IgA) deposits along the basement membrane zone, which typically distinguishes the disorder from dermatitis herpetiformis containing IgA in a granular pattern in the dermal papillary tips.

## TREATMENT

The treatment approach for immunobullous diseases is similar but depends significantly on the disease severity. The clinician

should aim to control blistering and discomfort while minimizing side effects from immunosuppression. If disease is limited, then moderate doses of daily prednisone in conjunction with topical clobetasol ointment 0.05% may be adequate. For standard disease, 1.0 mg/kg/day of prednisone can be started. A less traditional approach with fewer side effects may combine oral prednisone with oral nicotinamide and minocycline or doxycycline at 100 mg twice daily. Such antibiotics are often successfully employed in CBDC and BP in which oral steroids are often avoided. When disease activity is moderate to severe, then systemic immunosuppressants such as cyclosporine, mycophenolate mofetil, azathioprine, dapsone, and methotrexate are prescribed. For vulvar lesions in particular, local treatment with corticosteroids either topically or intralesionally (kenalog 15 mg/mL) may be effective.<sup>42</sup> Any concomitant infections should also be treated with appropriate antimicrobials.

## Epidermolysis Bullosa Acquisita

Epidermolysis bullosa acquisita (EBA) is an uncommon chronic severe immunobullous disease, which has been rarely described on the vulva. The clinical and the histological picture, including those of immunofluorescence, are similar to those of BP.<sup>44</sup>

It is caused by IgG autoantibodies directed against the noncollagenous amino-terminal (NC-1) domain of collagen VII, a major component of anchoring fibrils located in the lamina densa and sublamina densa region. Small group of patients demonstrate antibodies to the collagen domain or have IgA antibodies.<sup>45</sup>

## CLINICAL FEATURES

It is characterized by tense, subepidermal vesicles and bullae that heal with scarring and milia. Lesions may appear on any mucocutaneous surface and generally are distributed in anatomic areas subjected to repetitive minor trauma, such as the extensors of upper extremities. Clinical features of EBA are similar to those of BP, however the antibody binds to the floor of the blister, the dermal component.<sup>45,46</sup>

EBA can occur at any age, but it more frequently affects elderly patients. Childhood cases have been reported in the literature. In 1997, Park et al.<sup>44</sup> reported a case of a 6-year-old girl with EBA, who had lesions in the genital area.

## DIAGNOSIS

### Histopathology

Light microscopic examination of the tissue stained with hematoxylin and eosin reveals subepidermal bulla. The degree of associated inflammation on histology correlates closely with the clinical appearance of the lesion selected for biopsy. Classic EBA usually presents with a non- or pauci-inflammatory subepidermal blister, whereas the inflammatory form of EBA is associated with a neutrophil-rich infiltrate with variable

numbers of eosinophils.<sup>45</sup> Because histological findings of EBA are nonspecific, immunofluorescence and other testing modalities are required for definitive diagnosis.

### Immunofluorescence

DIF studies of perilesional skin demonstrate IgG, and to a lesser extent C3, deposits distributed in a thick continuous and linear pattern along the epidermal basement membrane zone. Less commonly linear deposits of IgA or IgM are found.

Indirect immunofluorescence (IIF) is approximately positive in about half of the affected patients. IIF reveals the presence of circulating IgG autoantibodies in the patient's serum that target type VII collagen of the basement membrane. IIF on salt-split normal human skin illustrates the binding of the circulating antibodies to the dermal side (lower part) of the artificial blister. IIF on salt-split skin helps differentiates EBA from BP, in BP IgG autoantibodies from the serum bind to the epidermal roof (upper part) of the bulla.<sup>45,46</sup>

### Differential Diagnosis

EBA must be differentiated from other diseases associated with subepidermal blisters like BP, MMP, porphyria cutanea tarda, bullous form of lupus erythematosus and dominantly inherited epidermolysis bullosa dystrophica.

### Management

The prognosis of EBA is very variable, but rarely life-threatening. The treatment of this chronic blistering dermatosis is challenging because of the rarity of the condition combined with the absence of published randomized, controlled therapeutic trials.

Options of treatment include systemic corticosteroids, other immunosuppressive agents, such as azathioprine, methotrexate, and cyclophosphamide. Because of its relatively benign side effects, colchicine has been used successfully in some patients. Dapsone, mycophenolate mofetil, rituximab, intravenous immunoglobulin, or cyclosporine have also been reported to have some benefit. Extracorporeal photochemotherapy may be helpful in EBA patients unresponsive to conventional therapy.<sup>45,46</sup>

### Hidradenitis Suppurativa “Acne Inversa”

Hidradenitis suppurativa (HS) is a chronic condition characterized by recurrent boils, sinus tracts formation and subsequently leading to scarring. HS occurs in the apocrine-bearing skin, such as the axillae, buttocks, groins, mammary and inframammary regions. In the female genital region it often affects the labia majora and natal cleft. It occurs in obese individuals, although this is not always the case. There may be a family history of this condition.<sup>47</sup>

HS was felt to be due to apocrine gland activity, but now it is recognized to be essentially follicular, we now know that occlusion of the follicular infundibula followed by rupture of the follicle is the inciting event.

In some patients, HS makes up one part of follicular occlusion syndrome when it is associated with acne conglobata, dissecting cellulitis, and pilonidal sinus.<sup>47</sup>

Some authors recommend abandoning the use of the name hidradenitis suppurativa and replace it with “acne inversa.” The term acne inversa links the pathogenesis to acne and reflects the fact that it is an expression of follicular occlusion in localizations inverse to acne vulgaris.<sup>48</sup>

### Epidemiology

HS starts around puberty and coincides with the post-pubertal increase in androgen levels. Average patient age is 23 years. Children are not affected unless they have precocious puberty. Women are affected three times as often as men.<sup>47</sup>

### Clinical Features

HS is characterized by the presence of painful subcutaneous nodules; with time these nodules may rupture resulting in deep dermal abscesses. After rupture, the lesions often extrude a purulent, foul smelling discharge. As the disease process continues, fibrosis, dermal contractures, and induration of the skin occur. The presence of double comedones is typical of the disease.<sup>47–49</sup>

### Histology

Follicular occlusion is prominent with keratin plugs, with dilatation of the follicular infundibulum. There is superficial and deep dermal perivascular infiltrate of neutrophils, lymphocytes, histiocytes, and plasma cells. Rupture of follicles results in perifollicular abscess, granulation tissue, and foreign-body giant cell reaction. Secondary involvement of apocrine glands occurs with dilatation of the glands and infiltrate of neutrophils in the walls and within the lumen.<sup>47,50</sup>

### Differential Diagnosis

In the early stages, a simple folliculitis may be suspected, but this usually has central pointing or ulceration and usually does not form sinus tracts. Other conditions with similar features include dermoid cyst, cutaneous blastomycosis, furuncles and lymphadenopathy.

In the chronic indurated lesions, often with sinus formation, Crohn disease should be considered. The two diseases may coexist. Other conditions, including granuloma inguinale (donovanosis), mycetoma, lymphogranuloma venereum, nocardial infection, noduloulcerative syphilis, and tuberculosis may resemble HS.<sup>47</sup>

### Management

Diabetes mellitus should be excluded. Medical treatment includes weight reduction if the patient is overweight. Intralesional injection of steroids may be helpful in early inflammatory lesions. Topical antibiotics, like clindamycin have proven beneficial in some patients.<sup>47,49</sup>

Systemic antibiotics, either alone or in combination are used. Recently, a combination of clindamycin and rifampicin has been suggested. Oral retinoids may have a role to play in the management of this disease. Systemic corticosteroids often lead to dramatic improvement. Dapsone was shown to be effective in some patients. Immunosuppressive drugs, like cyclosporine could be beneficial. The TNF-alpha inhibitors infliximab and etanercept have also produced favorable outcomes in HS.<sup>47,49</sup>

The best results seem to occur when the involved areas are surgically excised and closed primarily or grafted. The earlier in the course of the disease excision is performed the better. However, recurrence of the disease may be problematic. CO2 laser has been used successfully in HS, as well as Botulinum toxin A injection.<sup>47,49</sup>

## COMPLICATIONS

Observation and follow-up is necessary as a small number of these patients progress to develop malignancy, squamous cell carcinoma within the non-healing sinus tracts.<sup>51-53</sup>

The excessive scarring and fibrosis produced by HS lesions can lead to contractures and limitations in limb mobility, especially in the axilla.<sup>47,49</sup> In addition, inflammation and scarring in the genital region may predispose to anal, urethral, and rectal strictures. Urethral fistulas and vulvar lymphedema have also been reported in patients with HS.

## Crohn's Disease

Vulvar Crohn disease (CD) can present as an extension of gastrointestinal (internal) disease or metastatic CD (MCD). The condition has been reported in patients as young as 8 years old to 64 years old.<sup>54</sup> Nearly two-thirds of patients are premenopausal women.

## PRESENTATION

The presentation of vulvar CD is usually varied and difficult to diagnose, especially in cases of metastatic spread rather than direct or contiguous spread such as from fistula formation. In a recent review, metastatic spread was found to be by far the most common presentation, in 91% of cases (50 patients out of 55), while contiguous spread occurred in only 9% of the cases (5 patients).<sup>55</sup>

The length or specific "type" of previously active CD was not identified to predispose patients to CD of the vulva. Interestingly, 25% of patients with vulvar CD did not have any previous intestinal symptoms and had not been diagnosed with CD at the time of their vulvar symptoms.<sup>55</sup>

Involvement of the vulva can be the first and/or the only manifestation of disease.

Furthermore, vulvar CD can appear many years after a subtotal colectomy in patients with evidence of no other CD<sup>56</sup> or can persist despite excision of the intestinal disease or quiescent gastrointestinal disease.<sup>57</sup>

## SIGNS AND SYMPTOMS

There is no consistent correlation between the appearance of cutaneous lesions and intestinal disease activity.

CD of the vulva typically manifests with swelling, pruritus, erythema, and as a progressive and painful ulceration of the labia. These can often evolve into condyloma-like lesions and/or skin tags. Patients can also present a wide range of symptoms such as vaginal discharge, painful ulcerations, or a vulvar mass (Table 61.2).<sup>55</sup> Physical examination usually reveals an indurated area, localized or generalized edema of the labia, and ulcers that often extend into the groin. These signs and symptoms are also common to many other gynecological conditions making the clinical suspicion of vulvar CD very difficult. This results in delayed definitive diagnosis.<sup>58</sup>

## DIAGNOSIS

When these clinical features are identified, it is important to exclude other granulomatous diseases such as sarcoidosis, tuberculosis, lymphogranuloma venereum, pyogenic infections, HS, intertrigo, and syphilitic lesions. A biopsy of the lesion shows the typical non-caseating granulomas.

## DIFFERENTIAL DIAGNOSIS

The absence of comedones and bridging scars differentiates CD from HS. There may be no clinical evidence of bowel disease, but the edema and multiplicity of physical signs is often very suggestive of CD.

## TREATMENT

The natural course of vulvar CD is unpredictable. Some lesions may resolve spontaneously. The treatment relies mainly on medical therapy.

Systemic antibiotics such as ciprofloxacin and metronidazole may be helpful in managing the acute-on-chronic episodes in this nasty disease. The most successful treatment was achieved by metronidazole alone or in conjunction with oral or topical steroids with a success rate of 87.5%.<sup>55</sup> Systemic, intralesional, and topical corticosteroids,

**Table 61.2:** Signs and Symptoms at Presentation of 55 Cases with Vulvar Crohn Disease

Symptom	Total no. of patients (percentage)
Swelling	34 (61.8)
Ulcers	22 (40.7)
Pain	11 (20.3)
Pruritus	7 (12.9)
Erythema	8 (14.5)
Abscess	2 (3.7)
Discharge	3 (5.5)
Mass	2 (3.7)

Adapted from Andreani et al.<sup>55</sup>

5-aminosalicylic acid, and sulfasalazine are also among the medical therapies purported to be of benefit for MCD.<sup>59</sup>

Immunomodulating therapies, including the use of mercaptopurine, azathioprine, and anti-tumor necrosis factor, are being used in the medical management of CD.<sup>60</sup>

Surgical therapies for MCD have been tried for resistant cases. However, correlation between the appearance of cutaneous lesions and intestinal disease activity is quite variable<sup>61</sup>; thus, it is not surprising that surgical removal of diseased bowel does not always result in the improvement of MCD.

Surgical debridement of perianal CD was shown to be beneficial in those patients with co-existing abscess of the vulva.<sup>55</sup> Bowel surgery may be helpful, and in most unpleasant cases, vulvectomy may have to be resorted to,<sup>62</sup> although the cutaneous disease does tend to recur. The disease should be closely monitored, as cancers have been described.<sup>63</sup>

### Zoon Vulvitis (Vulvitis Circumscripta Plasma Cellularis or Plasma Cell Vulvitis)

This rare, chronic, benign inflammatory condition is much less common in women than its counterpart in men, Zoon balanitis. It was described both by Zoon in 1954 and Garnier in 1955.<sup>64,65</sup> Since that time, 34 cases of Zoon vulvitis have been reported in the literature in women ranging in age from 8 to 79 years. Its precise incidence is unknown.<sup>66</sup>

#### CLINICAL FEATURES

The condition may initially be asymptomatic. Symptoms include pruritus, dyspareunia, and dysuria. Clinically, these lesions are circumscribed, glistening, erythematous macules with a yellow or orange hue, occasionally with purpuric spots described as “cayenne pepper”<sup>66,67</sup> (Fig. 61.8). The lesions can be found on the labia minora and majora, clitoris, posterior fourchette, and urethral meatus.

#### ETIOLOGY

The exact etiology is unclear, but suggested predisposing factors include warmth, friction, poor hygiene, and herpes simplex and other chronic infections.<sup>65,66</sup>

#### HISTOLOGY

Zoon vulvitis is characterized by the dense subepithelial band-like (lichenoid) infiltrate with plasma cell predominance as the main histological feature. Epidermal thinning with small horizontally disposed lozenge-shaped keratinocytes, mild spongiosis, vascular dilatation, and red cell extravasation with hemosiderin deposition are considered further distinctive criteria. While reactive epithelial changes may be present, true dysplasia is absent.<sup>67</sup>

#### DIFFERENTIAL DIAGNOSIS

The differential diagnosis should include Paget disease, pemphigus vulgaris, LP, fixed drug eruption, squamous carcinoma, and herpes

**Fig. 61.8:** Plasma cell vulvitis, with beefy erythematous plaques. *Courtesy: Andrew Goldstein, MD.*

simplex infection. The diagnosis should be considered in any patient with an erythematous lesion and intractable vulvar pruritis.<sup>65,66</sup>

#### MANAGEMENT

Response to therapy is inconsistent. Reported treatments include topical,<sup>67</sup> intralesional and systemic corticosteroids, antifungal agents, antibiotics, etretinate, interferon, vaginal estrogen, topical calcineurin inhibitors (Tacrolimus),<sup>68</sup> and immunosuppressive agents. Destructive modalities like fulguration, laser ablation, cryotherapy and surgical resection have been suggested. To date there are two cases that cleared completely after using high potency topical steroids.<sup>69</sup>

### Behçet Disease (BD)

This disease was named in 1937 after the Turkish dermatologist Hulusi Behçet, who first described the triple-symptom complex of recurrent oral aphthous ulcers, genital ulcers, and uveitis.<sup>70</sup> Later, it was recognized as a multisystem disease. The diagnosis is made on the basis of criteria proposed by the International Study Group for Behçet syndrome in 1990.<sup>71</sup> In order that a diagnosis of Behçet syndrome might be made, oral ulceration will exist in association with two of the following: recurrent genital ulceration, cutaneous lesions and eye lesions, and a positive pathergy test.

Table 61.3 describes the criteria required for the diagnosis of Behçet syndrome.

Bipolar aphthosis of Neumann is considered as a *forme fruste* of BD. It is characterized by oral and genital ulcers without any other manifestations. BD is most prevalent (and more virulent) in the Mediterranean region, Middle East, and Far East.<sup>72</sup>

**Table 61.3:** International Study Group Criteria for Behçet Disease

Finding	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulcers observed by the physician or patient, which have recurred at least three times over a 12-month period
Recurrent genital ulceration	Aphthous ulceration or scarring observed by the physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in the vitreous on slit-lamp examination; or retinal vasculitis detected by an ophthalmologist
Skin lesions	Erythema nodosum observed by the physician or patient, pseudofolliculitis, or papulopustular lesions; or acneiform nodules observed by the physician in a post-adolescent patient who is not receiving corticosteroids
Positive pathergy test	Test interpreted as positive by the physician at 24 to 48 hr

### ETIOLOGY

Susceptibility to BD is strongly associated with the presence of the human leukocyte antigen (HLA)-B51 allele and its presence is also strongly associated with a more aggressive course. The cause of BD is however still unknown. Infections, both viral and bacterial, may play a role.<sup>72</sup>

### CLINICAL PRESENTATION

The genital ulcers are seen in about 60–90% of patients with Behçet syndrome and morphologically resemble oral aphthae. The ulcers are painful and heal with scarring.<sup>72</sup>

**Fig. 61.9:** Vulvar ulceration in patient with Behçet disease. Courtesy: Andrew Goldstein, MD.

These ulcers can be located on the vulva, vagina, cervix, or groins, but the most common location is on the vulva (Fig. 61.9). Ulcers on the female patient tend to be larger and deeper than in the males with genital lesions, sometimes even leading to perforations. When located in vagina, they may lead to urinary/fecal fistulae formation. The size of these ulcers is usually 1–2 cm.<sup>72,73</sup>

Superadded sexually transmitted infection may be a concern as the epithelial barrier is lost in recurrent genital ulcers due to BD.<sup>74</sup> Intractable postcoital bleeding due to Behçet vaginal ulcer requiring surgical intervention has been reported in a woman.<sup>75</sup>

### MANAGEMENT

Usually the ulcerations heal spontaneously. With regard to treating the symptoms and healing of genital aphthae, local treatments as described for aphthae may be used. Topical steroids are usually effective for mucocutaneous involvement. Some patients respond insufficiently and additional treatment may be necessary in these cases.<sup>76</sup>

Colchicine is known to be beneficial in mucocutaneous disease,<sup>77</sup> in a double-blind trial with 116 patients in 2001,<sup>78</sup> Yurdakul and colleagues found that colchicine reduced the occurrence of genital ulcers, erythema nodosum, and arthritis in both men and women. Other available alternatives like aspirin, dapsone, levamisole, thalidomide, cyclosporine, interferon-alpha (IFN-alpha) and TNF blockers have all been reported to be helpful.<sup>72,76</sup>

### Aphthous Ulcers

Aphthous ulcers can present as minor and major type. The latter is associated with more severe pain and scarring. The etiology is unclear. Some believe that these ulcers are a result of a dysfunction of the immune system, resulting in immunologically mediated damage to epithelial cells. This reaction may be triggered by trauma, hematinic (e.g., iron, folate, or vitamin B<sub>12</sub>) deficiencies, hormonal fluctuations, psychological stress, infectious agents, food hypersensitivities, genetic factors, and HIV infection. The lesions are recurrent and they may correlate with the menstrual cycle.<sup>79</sup>

### CLINICAL FEATURES

As a rule, aphthous ulcers are painful, they are mostly 5 mm in diameter but may vary in size from 3 to 10 mm (larger ulcers are termed major aphthae). The ulcers are round, shallow, and sharply defined with a yellow base and a red halo. Usually one to five lesions occurs per attack; however, they may occur in any number. The lesions tend to involute in 1–2 weeks, but recurrences are common<sup>79</sup> (Figs. 61.10a and 61.10b).

### HISTOPATHOLOGY

Histopathological examination of the biopsy specimen does not reveal unique findings and is rarely indicated, except to exclude other diagnoses, such as pemphigus, cicatricial pemphigoid,

\*c+

\*d+

**Figs. 61.10(a) and (b):** Vulvar aphthous ulcers. *Courtesy: Andrew Goldstein, MD.*

carcinoma, and BD. Histologically, the lesions consist of dense perivascular and interstitial lymphocytic inflammatory infiltration in the sub mucosa with occasional plasma cells.<sup>79,80</sup>

### DIFFERENTIAL DIAGNOSIS

Includes common viral infections (e.g., HSV), physical trauma, autoimmune blistering disorders (e.g., pemphigus vulgaris, cicatricial pemphigoid), LP, and erythema multiforme. In the case of multiple major mucosal aphthous ulcers (oral and genital), it might be difficult to distinguish this condition from BD. Extensive and painful aphthosis may occur in patients with HIV.<sup>80</sup>

### MANAGEMENT

No cure is available. Several topical agents will lessen the pain. Locally applied corticosteroids usually improve the patient's

symptoms. Application of topical anesthetics, like 5% lidocaine ointment, are useful. In severe cases, systemic therapy with dapsons, colchicine and thalidomide have been used.<sup>80</sup>

## Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is a rare cause of vulvar ulceration. There are few cases of vulvar involvement described in the literature.<sup>81–83</sup> It is important to differentiate this from an infective lesion as the treatment of PG is with systemic corticosteroids and immunosuppressive agents.

### CLINICAL FEATURES

PG manifests as painful cutaneous ulceration with undermined edges, irregular margins, ragged purple overhanging edge and necrotic tissue at the base. Lesions can present as single or multiple small ulcers.

Classic PG begins as an inflammatory pustule with a surrounding halo that enlarges and begins to ulcerate. A primary lesion may not always be seen, and a substantial proportion of lesions appear at the sites of trauma (pathergy).<sup>81–83</sup>

### ETIOLOGY

The pathophysiology of PG is unknown, but altered immune system is believed to be involved. Most common is an association with systemic diseases, especially arthritides (seronegative and seropositive), inflammatory bowel disease and hematological disorders (leukemia and monoclonal gammopathies). Less commonly associated diseases include hepatic diseases, myelomas, immunological diseases, and HIV infection. Screening tests for underlying diseases should be performed.

### HISTOLOGY

There may be signs of vasculitis, but most commonly only chronic inflammation is seen.

Early histopathological feature is dermal neutrophilic abscess; later biopsies demonstrate epidermal necrosis and ulceration, superficial dermal edema, and a dense, mixed dermal infiltrate. Histopathological findings are not specific but crucial to rule out other causes of skin ulcers.<sup>84</sup>

### DIFFERENTIAL DIAGNOSIS

The clinical picture of PG, in the classic ulcerative form, is characteristic. As there are no diagnostic serological or histological features, PG mostly remains a diagnosis of exclusion.

Multiple infections (e.g., viral: herpes, bacterial: cellulitis), syphilis must be excluded. Various forms of cutaneous vasculitis, vulvar ulcerations in patients with BD and other types of neutrophilic dermatoses like Sweet syndrome may produce similar clinical picture.<sup>85</sup>

## TREATMENT

Associated underlying conditions should be sought, even if no symptoms are found. The nature and intensity of the therapeutic approach depend on the number, size and depth of the lesions, the rate of expansion and appearance of new lesions, the associated disorder, the medical status of the patient, and the risk and patient's tolerance of prolonged therapy.

The standard treatment of PG is local or combined local and systemic corticosteroid therapy with or without adjunctive systemic immunosuppressive therapy.

In mild cases, application of topical corticosteroid, intralesional steroid injections, or topical tacrolimus may be beneficial. Systemic high dose corticosteroids can be very effective. A dramatic improvement with corticosteroid treatment supports the diagnosis of PG.

Other alternative systemic treatments, used in cases resistant to corticosteroids or in cases with severe corticosteroid side effects, are cyclosporine A, azathioprine, cyclophosphamide, and chlorambucil, which have been reported to be effective. Cyclosporine and infliximab result in faster healing and are considered the immunosuppressives of choice for managing severe or refractory PG.<sup>81–84</sup>

## Lupus Erythematosus

The prevalence of vulvar involvement in patients affected with systemic lupus erythematosus (LE) is unknown, and there are a limited number of cases in the literature on genital lupus.

In 1989, Burge et al.<sup>86</sup> published a series of reports on 121 patients affected with lupus (both males and females), the group found that 21% of patient with systemic lupus and 24% of those with chronic cutaneous LE (CCLE) had mucosal involvement. There were no specific genital lesions found in 48 females with systemic LE, although one patient had vaginal lesions possibly secondary to Sjogren syndrome. However, vulvar lesions were identified in 2 of 42 patients with CCLE. One patient had erythema and painful ulceration near the vaginal introitus, while the other had lacy LP-like plaques on the vulval mucous membranes.

Discoid lupus lesions have been reported on the female genitalia. Bilenchi in 2004<sup>87</sup> reported a case of a patient with history of discoid LE, who developed discoid lesions on the labia majora. Jolly and Patel in 2006<sup>88</sup> reported a single case of a patient with systemic LE who developed discoid LE lesions on the left labium majus (Fig. 61.11).

## Dermatomyositis

In 1985, Lavery et al.<sup>89</sup> reported the only case in the literature of dermatomyositis involving the vulva. Dermatomyositis may be associated with an underlying malignancy, and Celebi et al. in 2001<sup>90</sup> reported a case of its occurrence in a patient with cervical carcinoma. Wishart in 1973<sup>91</sup> reported a case of a 42-year-old female with dermatomyositis who developed reticular cell sarcoma (reticulosarcoma) of the vulva after five months of azathioprine therapy.

**Fig. 61.11:** Clinical appearance of discoid genital plaque in a patient with systemic lupus erythematosus. With permission from Jolly M and Patel P.<sup>88</sup>

## Estrogen-Mediated Cyclical Vulvitis

Fischer et al. in 2000<sup>92</sup> has described a group of women who had either treatment resistant cyclical vulvitis or a vulvitis provoked by hormone replacement therapy (HRT). Intradermal testing with endogenous estrogens demonstrated delayed type hypersensitivity responses. Two of the patients reacted to intradermal testing with progesterone.

## DIFFERENTIAL DIAGNOSIS

Candidal vulvitis and Zoon vulvitis should be differentiated with appropriate swabs and biopsies.

## MANAGEMENT

In this small group described above, one improved at menopause. Those with HRT provoked disease resolved on cessation of HRT. Three responded to lowering their endogenous estrogen levels, and one controlled her symptoms with a potent topical corticosteroid.<sup>92</sup>

## Conclusion

Vulvar dermatoses are a diverse group of pathology. The vulva can be affected by an inflammatory, infectious, or neoplastic process. Symptomatology is highly variable. The presentation may range from asymptomatic, pruritic, ulcerative, to a chronic disabling condition. The vulva can be a clue to an underlying systemic disease, and careful examination of the anatomic structures is valuable for the treating clinician. Due to the personal nature of symptoms, many patients are hesitant to discuss their symptoms with a healthcare provider. Similarly, some clinicians feel challenged with respect to the management of vulvar diseases. Therefore, it is important that practitioners receive training and gain experience in diagnosing and treating these diseases.

# Vulvar Vestibulitis Syndrome

Jorma Paavonen • Leila Unkila-Kallio • Päivi Tommola

# 62

## Introduction

Vulvar vestibulitis syndrome (VVS) is a subset of vulvodynia. VVS is a common but often poorly recognized cause of dyspareunia in premenopausal women. VVS causes severe dyspareunia and thereby affects sexual and reproductive life of predominantly young women. Thus, VVS has a major impact on women's psychological well-being, self-esteem and general quality of life. Unfortunately, VVS largely remains an ignored health problem. Prevalence rates have been poorly studied, but some studies suggest that the rates vary from 9.8%<sup>1</sup> to 15% in general gynecologic practice.<sup>2</sup> In the late 19th century, VVS had already been described in the literature.<sup>3</sup> The etiology or etiopathogenesis is unknown. Although many sexually transmitted viral or bacterial pathogens have been linked to VVS, no evidence supports causative role for any specific micro-organisms. However, the clinical symptoms and signs are straightforward. The diagnosis is based on symptoms such as severe pain on vestibular touch or vaginal entry, tenderness to pressure on the vulvar vestibule, and vulvar erythema of varying degrees.<sup>4</sup> Because the underlying pathophysiology remains unclear, treatment is challenging.

The classification and terminology of vulvodynia has changed during the past few decades starting from the consensus of the International Society for the Study of Vulvovaginal Disease (ISSVD) in 1976 to introduce the term burning vulva syndrome. The latest recommendation provided in 2003 by ISSVD uses the term vulvodynia and classifies subsets on the basis of the site involved. Pain can be generalized or localized when it is restricted only to a limited vulvar area, e.g., vestibule or clitoris. Both generalized and localized pain can be spontaneous or provoked.<sup>5</sup> In the literature the term VVS is widely used for localized provoked vestibulodynia and dysesthetic vulvodynia is used for the generalized spontaneous vulvodynia. These terms are still clinically relevant and useful in clinical practice.

## Vulvar Anatomy

The vulva is the anatomic region between mons pubis in the front and anal orifice in the rear (Fig. 62.1). It includes perineum, labia

majora, labia minora, clitoris and vestibule. The vulvar vestibule may be defined as a ring-like portion of the vulva that extends laterally from the hymenal ring to a line of more keratinized skin on the labia minora, the Hart line. Anteriorly the vestibule reaches upward to the frenulum of the clitoris in the anterior commissure and posteriorly downward to the fourchette and the mucocutaneous Hart line. The vestibule contains urethral meatus, vaginal introitus delineated by the hymen, and vestibular glands. Major vestibular glands are the Skene glands paraurethrally and Bartholin glands with openings adjacent to hymen at 5 o'clock and 7 o'clock. Minor vestibular glands are scattered throughout the vestibulum. Embryologically vestibule differentiates from the urogenital sinus and is thus of endodermal origin, which makes it different from the surrounding vulva which is ectodermal origin. The vestibule is covered with a layer of nonkeratinized stratified squamous epithelium and is richly innervated.

**Fig. 62.1:** Anatomic landmarks of the vulva. Modified from *Modern Colposcopy, Textbook and Atlas* (ref. 7, p. 450).

## Histopathology of Vulvar Vestibulitis

The standard histopathologic examination reveals mild to moderate chronic inflammation with mainly subepithelial lymphocyte infiltrates around minor vestibular glands in patients with vulvar vestibulitis. High numbers of mast cells are present. Increased numbers of nerve bundles and nerve endings beneath and in the vestibular epithelium have been demonstrated by immunohistochemistry.<sup>6</sup>

## Conservative Treatment Modalities

Progress in the treatment of VVS has been unsatisfactory. A wide variety of local and systemic medical, cognitive-behavioral, surgical, and alternative treatment modalities have been proposed and some treatment guidelines have been developed.<sup>7,8</sup> However, these have mostly been based on anecdotal clinical observations and uncontrolled data from case series or case-control studies. Randomized treatment trials are few. Increasing interest has been focused on behavioral and cognitive-behavioral treatments as well as biofeedback with or without electromyographic equipment. This has provided alternative management options. The goal of all management options is to improve psychological adjustments and sexual functioning and thereby reduce pain or increase pain tolerance. Discontinuation of oral contraceptives is often helpful and should be recommended. However, the success rate of conservative treatment modalities has been poor, particularly in severe cases with long history of symptoms. Since 1981, many studies have focused on surgical treatment with encouraging results.

## Surgery

Surgery by vestibulectomy has been considered as “the last resort” in the management of patients not responding to conservative treatment modalities. Several vestibulectomy techniques have been described. However, specific surgical technique as such plays relatively small role in the overall outcome. Overall, surgery by vestibulectomy seems to be surprisingly effective with high success rates.<sup>9</sup> However, lack of randomized trials and insufficient data on complication rates must be emphasized. In 1981, Woodruff et al.<sup>10</sup> reported a case series of patients with dyspareunia treated by perineoplasty operation. Several modifications of the original operation have been reported.<sup>9</sup> In the posterior vestibulectomy operation the excised area includes only the posterior part of vestibule from approximately 10 o'clock to 2 o'clock inside the Hart line. This modification was developed in hope of shorter operation time and less intraoperative and postoperative complications. Also, most women with dyspareunia complain symptoms only in the posterior vestibule.<sup>11</sup> Vestibulectomy always involves vaginal advancement.

Complication rates have not been systematically reported in most vestibulectomy studies. Hemorrhage, hematoma formation, wound infection, and need for resuturation are the most common short-term complications.<sup>9</sup> Because the ducts of the Bartholin glands are invariably transected in vestibulectomy or perineoplasty operations, Bartholin cyst formation from duct occlusion may be inevitable after few months or years, and often requires

operative repair.<sup>12</sup> However, more studies and data on long-term complications of surgical treatment of VVS are needed. In addition to evaluating complication rates more systematically, surgical success should be defined with many different outcome measures, such as improvement of sexual functioning, correction of vestibular tenderness, and overall patient satisfaction. However, operative treatment provides significant relief in dyspareunia in most patients (80% or more in 17 of 33 studies).<sup>9</sup> Better sex life or better sexual functioning has been an additional outcome measure, and improved significantly in all studies.<sup>9</sup> Overall patient satisfaction rates are around 90%.<sup>9</sup> No relief or worsening of dyspareunia is defined as unsuccessful outcome and varies from 0% to 16%.<sup>9</sup>

## Pelvic Floor Muscle Dysfunction and Vaginismus

Pelvic floor muscle dysfunction is often a concomitant problem in patients suffering from vestibulitis and most treatment guidelines recommend biofeedback. Postoperative biofeedback by physical therapy increases the success rate after vestibulectomy. Thus, pelvic floor muscle dysfunction should be recognized. On the other hand, vaginismus patients should always be evaluated for vestibulitis as a possible reason. Strikingly, this was totally ignored in a recent review about the diagnosis and management of vaginismus.<sup>13</sup>

## Psychosexual Aspects

Psychosexual problems challenge the success of any treatment modality. Cognitive-behavioral therapy (CBT) alone has significantly reduced complaints in a large number of patients.<sup>14</sup> If this therapy was combined with surgery, the intervention would be successful in all patients. Although in a randomized study comparing results of vestibulectomy, electromyographic biofeedback, and group cognitive-behavioral therapy, vestibulectomy was superior to other treatment modalities in reducing pain, all three groups improved on psychological adjustment and sexual functioning after 6 months.<sup>15</sup> The treatment gains were maintained or even improved after a follow-up of 2.5 years. In reducing self-reported pain during intercourse, vestibulectomy was no more superior to CBT after longer follow-up.<sup>16</sup>

## Other Aspects

Although surgery is effective in reducing pain, other treatment modalities are also needed to maintain satisfactory outcome. Constant pain has been an exclusion criterion for surgery in many studies. However, the differentiation between VVS, e.g., locally provoked vestibulodynia and unprovoked generalized vulvodynia, e.g., dysesthetic vulvodynia, is not always easy. Some patients certainly have a mixture of both types of the disease and sometimes the tendency for provoked pain is so strong that it is caused even by a minor pressure, for example, from underwear resulting in a false experience of constant pain. When comparing patient characteristics between the groups with successful and unsuccessful results, surgery fails among women who have constant pain in addition to dyspareunia.<sup>17</sup> Patients' willingness to attend psychological evaluation before surgery

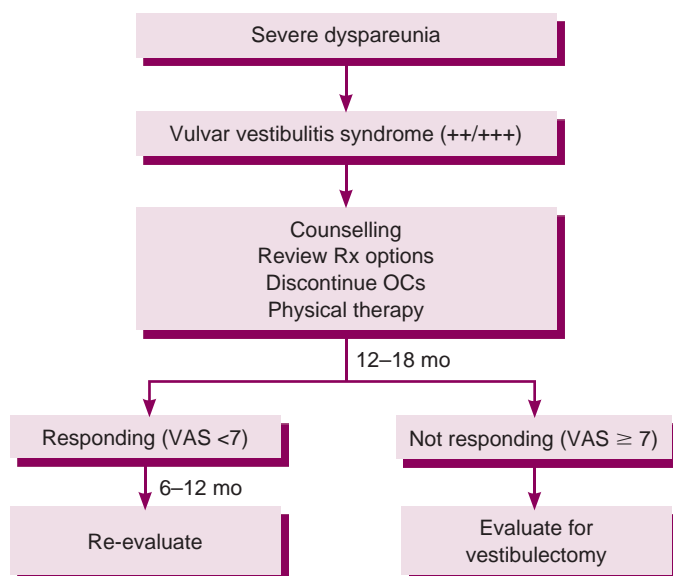

also predicts favorable outcome. Women who understand that the cause of pain is multidimensional are probably more willing to take an active role in rehabilitation efforts after surgery and end up with better outcome.

## Current State of Art

VVS is an important but often ignored cause of severe dyspareunia in young women. Multiple anecdotal conservative treatment modalities have been used with relatively poor success rates. Characteristic clinical criteria for vulvar vestibulitis, uniform symptoms and signs, and long history of severe dyspareunia have been the clinical prerequisites for operative treatment. Surgical treatment has in general been offered to the most severe cases with no response to conservative treatment modalities. Because the definition of successful outcome varies and complications are rarely analyzed, it is somewhat difficult to compare individual studies. One major problem is the lack of randomized studies. Most studies of vestibulectomy report strikingly high success rates and low recurrence rates. We have recently developed an algorithm for evaluation and management of patients with severe VVS, which has proven very useful in clinical practice (Fig. 62.2).

## Conclusions

All chronic pain issues are complex and certainly vulvodynia and vestibulitis represent one of the most challenging chronic pain syndromes. In addition to painful intercourse these women suffer from poor sexual health and poor quality of life. Although surgery improves the pain in most patients, other treatment modalities are often needed in the management. For some patients, conservative modes, e.g., behavioral therapy, sexual counseling, and biofeedback offer relief and improve the quality of life. However, anxious and desperate patients should not be denied the option of surgery.

**Fig. 62.2:** Clinical algorithm for evaluation and management of patients with severe VVS.

## Summary

Vulvar vestibulitis syndrome, a subset of vulvodynia, is a complex pain syndrome. It causes severe dyspareunia and mainly affects young women. The etiology is unknown and no uniformly effective treatment exists. Surgery has been considered as “the last resort” in the management of patients not responding to various conservative treatment modalities. Surgical treatment of vulvar vestibulitis by vestibulectomy has evolved through the years. Surgery is surprisingly effective and provides more satisfaction than any of the conservative treatment modalities available. However, lack of randomized trials of surgery vs. conservative treatment and insufficient data on complication rates associated with surgery must be emphasized.

## Male Genital Pain Syndromes

G.A. Luzzi • D. Mandal

### Introduction

Chronic genital and pelvic pain is a relatively common condition of otherwise healthy adult males, and is capable of substantial morbidity. The term 'chronic prostatitis' is often applied in this group of patients, sometimes loosely, and until recently, agreed definitions for prostatitis and pelvic pain syndrome in men have not been available. It is useful to subdivide the major syndromes into acute and chronic bacterial prostatitis (CBP), chronic pelvic pain syndrome (CPPS), and isolated testicular pain syndrome.

### History and Nomenclature

For several decades, it has been recognized that the prostate may be the focus of acute infection, of recurrent infection, and possibly the cause of persistent perineal and penile pain in men. In 1968, Meares et al. reported the development of a 4-glass test to identify prostatic infection and inflammation, and subsequently proposed a classification of prostatitis syndromes based on categorizing chronic prostatitis according to the results of the test.<sup>1,2</sup> Over the subsequent 20 years, a range of terms has been used to denote the various sub-categories of prostatitis, including chronic non-bacterial prostatitis, chronic abacterial prostatitis, and prostatodynia. Criteria for inclusion in these categories, and for the diagnosis of CBP, have varied, making comparisons between published studies difficult and presenting problems in the interpretation of published data on treatment studies and their outcomes. In 1995, the National Institutes of Health (NIH) in the US recommended new definitions and terminology, proposing that chronic non-bacterial prostatitis and prostatodynia should be renamed as CPPS, subdivided into inflammatory and non-inflammatory categories, respectively (Table 63.1).<sup>3</sup> Acute bacterial prostatitis (ABP) denotes acute infection of the prostate; CBP denotes recurrent prostatic infection. CPPS is defined as otherwise unexplained genital or pelvic pain (in or around the penis, perineum, scrotum) lasting for at least 3 months in males of at least 18 years of age. The distinction between inflammatory and non-inflammatory CPPS is based on the finding of white cells in the semen, expressed prostatic secretions (EPS), or in the urine

after prostatic massage. In asymptomatic inflammatory prostatitis, there are no symptoms, but white cells are found in the EPS, semen, or prostatic tissue during evaluation for other disorders.

### Epidemiology

ABP is an uncommon complication of urinary infection, whose exact incidence is unknown. CBP has been reported to represent 5–10% of patients evaluated for prostatitis in hospital-based series.<sup>4,5</sup> However, because diagnostic criteria have varied, this is unlikely to be a reliable estimate. In any case, such estimates can only give a rough idea of the relative incidence of CBP in comparison with other categories of chronic prostatitis (i.e., CPPS) and can tell us little about the incidence of CBP in the general population, which remains unknown. CBP is an uncommon condition, whose frequency may have fallen since the advent of quinolone antibiotics. In contrast, it is clear from hospital-based series and population studies that CPPS is a highly prevalent condition. It accounts for 90–95% of patients in hospital series, and the inflammatory subcategory, based on the finding of white cells in the EPS, was reported to account for around two-thirds of this group. A study of outpatient visits across the US demonstrated that in men aged below 50 years, prostatitis was the most common genitourinary diagnosis made by primary care physicians and urologists.<sup>6</sup> Using a validated chronic prostatitis symptom index developed by a multicenter

**Table 63.1:** NIH Classification of Prostatitis Syndromes<sup>3</sup>

Category	
I	Acute bacterial prostatitis
II	Chronic bacterial prostatitis (CBP)
III	Chronic pelvic pain syndrome (CPPS)
IIIA	CPPS, inflammatory* (formerly, chronic nonbacterial prostatitis)
IIIB	CPPS, non-inflammatory† (formerly, prostatodynia)
IV	Asymptomatic inflammatory prostatitis†

\*Leukocytes in expressed prostatic secretions (EPS), post-prostatic massage urine (urine-3, see Box 63.1), or semen.

†Leukocytes not found in EPS, urine-3, or semen.

collaboration in the US, a survey of nearly 3000 randomly selected Canadian men reported a prevalence of CPPS-type pain in approximately 10% of respondents.<sup>7,8</sup> The response rate was 29%, suggesting a minimum prevalence of 2.8%. Similar prevalences have been suggested by surveys using the same instrument in the US and Singapore (2.3–2.5%).<sup>9,10</sup> On the available evidence, it is reasonable to assume that perhaps 1 in 40 otherwise healthy men experience symptoms suggestive of CPPS at any given time.

## Clinical Features

### ACUTE PROSTATITIS

Acute prostatitis typically presents with the sudden onset of symptoms suggesting acute urinary tract infection (UTI; frequency, urgency, and dysuria) with additional features suggesting prostatic involvement (penile and perineal pain).<sup>11,12</sup> Obstructive urinary symptoms may supervene, including acute urinary retention. Systemic symptoms may be prominent with fever, rigors, and other features of bacteremia. On physical examination, the diagnosis is suggested by the finding of a swollen, tender prostate on digital rectal examination.

### CHRONIC BACTERIAL PROSTATITIS

CBP should be suspected in men with recurrent bacterial UTIs, when the same bacterial organism is isolated from urine cultures on repeated occasions, and in whom a predisposing structural reason for recurrent UTI is not demonstrated on examination by urinary tract imaging. Although patients are frequently symptomless in between recurrences of urinary infection, they may also report symptoms suggesting prostatic involvement, including perineal and penile pain.<sup>11,12</sup>

### CHRONIC PELVIC PAIN SYNDROME

The presence of otherwise unexplained genital or pelvic pain is central to the diagnosis of CPPS. The pain is typically perineal or penile, but may be widely distributed below the belt (Table 63.2). The quality of the pain is highly variable, and may be described as aching, or like a pressure. Sharp or short-lived pain may also be reported, as may dysesthetic features such as burning and tingling. It is useful to consider the pain as part of a characteristic triad in association with urinary and sexual dysfunctions. Urinary dysfunction is usually mild and includes frequency, urgency, feelings of incomplete bladder emptying, and reduced or variable urinary stream. Sexual dysfunction includes pain during or after ejaculation and changes in the color or consistency of the semen. CPPS is occasionally associated with intermittent blood staining of the semen (hematospermia). Erectile dysfunction is reported by a significant minority, 20–40% in published series of men with CPPS.<sup>13,14</sup> Erectile dysfunction in this context is often transitory. On examination, there are frequently no abnormal physical findings. The prostate may be tender to palpation, and prostatic pressure may provoke penile tip pain.

**Table 63.2:** Symptoms of Chronic Pelvic Pain Syndrome<sup>12</sup>

Genital or pelvic pain
Perineal
Penile tip, shaft or base
Testicular
Inguinal
Suprapubic or retropubic
Upper thighs
Rectal
Low back
Urinary dysfunction
Frequency
Urgency
Incomplete bladder emptying
Poor or variable stream
Urethral discharge
Sexual dysfunction
Pain during or after ejaculation
Discoloration of ejaculate
Hematospermia
Erectile dysfunction

The symptoms of CPPS are typically highly variable and usually run a chronic remitting and relapsing course; however, some patients experience constant symptoms and others report intermittent episodes with complete periodic remissions. The potential sickness impact of CPPS is considerable, and was demonstrated in one study to be comparable to that of chronic diseases such as Crohn disease or angina.<sup>15</sup> Patients may report exacerbating factors including posture (e.g., sitting or driving for long periods) and dietary factors (e.g., spicy foods, caffeine, or alcohol). Symptoms frequently persist for months or years. Natural history studies suggest that 40–50% of men with CPPS report improvement in symptoms after one year of follow-up, regardless of treatment.<sup>16,17</sup>

## Pathogenesis

### ACUTE BACTERIAL PROSTATITIS

ABP is most often an uncommon complication of UTI. The prostatic ducts communicate with the prostatic urethra, and therefore infected urine can gain access to the prostate. Consequently, the range of pathogens that cause ABP reflects the spectrum causing urinary infections; these are mostly *Escherichia coli* and other gram-negative rods, which account for more than 80%. *Proteus*, *Klebsiella*, and *Pseudomonas spp.* may all cause ABP.<sup>18</sup> Enterococci, *N. gonorrhoeae*, and anaerobes such as *Bacteroides spp.* may also do so. Rarely, acute prostatitis may arise following bloodborne spread in bacteremic or septicemic illnesses, for instance caused by *Staphylococcus aureus*. ABP may be complicated by the development of a prostatic abscess.<sup>19</sup>

## CHRONIC BACTERIAL PROSTATITIS

In CBP, a nidus of infection becomes established in the prostate and causes relapsing illness. This may follow an acute UTI or episode of ABP, after failure of antibiotic treatment to clear the prostate of infection. The prostate is a deep site which may be relatively inaccessible to certain antimicrobials. CBP may be associated with abnormalities of the prostatic architecture, including fibrosis, microabscess formation, and the presence of prostatic calculi or calcification. The incidental finding of prostatic calculi or calcification is very common in older men.<sup>20</sup> Prostatic calculi may form a source for recurrent bacteriuria.<sup>21</sup> The range of organisms that cause CBP, like ABP, is similar to those causing UTIs and therefore gram-negative rods, especially *E. coli*, are the commonest pathogens.<sup>22</sup> Enterococci may also be responsible. The role of gram-positive cocci is controversial. Ultrastructural studies in antibiotic-refractory CBP have demonstrated persistence of gram-positive cocci in prostatic tissue, in the form of polysaccharide-coated microcolonies.<sup>23</sup> These patients may not have a history of recurrent bacteriuria and the significance of the histological findings is debatable. In CBP, a range of prostatic fluid changes have been described, including a rise in pH and depletion of some components including zinc and a prostatic antibacterial factor.<sup>24</sup> Although zinc treatment was proposed on the basis of these findings, oral supplementation with zinc does not alter prostatic zinc levels and there is no evidence for benefit. Fungal infections may cause chronic prostatitis, especially in the immunosuppressed patients (such as patients with advanced HIV infection).<sup>25,26</sup>

## CHRONIC PELVIC PAIN SYNDROME

The cause of the much commoner CPPS remains unknown despite 20 years of investigation. White cells may be detected in the EPS of the majority of men with CPPS, with a predominance of polymorphs, and a smaller proportion of macrophages (which may be lipid laden) on Gram staining. Immunocytological analysis of the cells obtained after prostatic massage in men with inflammatory CPPS has shown that the spectrum is made up of mostly granulocytes (82%), with macrophages (11%), and also small numbers of T-lymphocytes (5%) and B-lymphocytes (2%).<sup>27</sup> The cause of the inflammatory response is not known, and understandably, its presence has stimulated a search for occult infection. Although some research groups have reported detection of *Chlamydia trachomatis* or *Ureaplasma urealyticum*, these findings have not been reproduced in other detailed studies and the balance of evidence would suggest that they are not significant causes of CPPS.<sup>28,29</sup> Using molecular detection techniques on prostatic tissue in men with inflammatory CPPS, the presence of DNA sequences common to a range of bacteria was reported in 1996.<sup>30</sup> In this study, which included men with inflammatory CPPS and without urethritis, only 4 of the 135 (3%) had *C. trachomatis* DNA detectable by polymerase chain reaction in prostatic tissue obtained by transperineal biopsy. *Ureaplasma* was not detected. The bacterial sequences that were commonly

found related to unusual organisms that did not represent possible contamination by skin or fecal commensals. Although the findings suggest a possible etiology implicating unusual, non-culturable bacteria, their significance is uncertain because similar DNA sequences have been detected in men without inflammatory CPPS, for instance in prostate tissue derived from men who underwent prostatectomy for prostate cancer.<sup>31</sup>

Although the cause of the inflammatory reaction in CPPS remains unknown, a central role for the inflammatory response in this condition is supported by the finding of elevations in certain pro-inflammatory and anti-inflammatory cytokines. Several investigators have reported similar results, with elevations in interleukin-1b and TNF-alpha in EPS and semen, and tissue markers of cellular activation in prostatic biopsies.<sup>32–34</sup> Interleukin-6, interleukin-8, and interleukin-10 have also recently been reported to be elevated.<sup>35,36</sup> Some of these cytokines are thought to have an anti-inflammatory role, and their elevation implies production to counterbalance the effects of the pro-inflammatory mediators. It is noteworthy that these elevations have been detected not only in men with inflammatory CPPS but also in those with no white cells detectable in the EPS, although at a lower level.<sup>32,33</sup> This suggests a common pathogenesis for inflammatory and non-inflammatory CPPS, and undermines the value of making a distinction between the two entities, which have the same clinical symptomatology. Moreover, whereas white cells do not correlate with presence or severity of symptoms,<sup>37</sup> it has been reported that cytokine levels in CPPS may correlate with symptom severity.<sup>37,38</sup>

Animal models, using mice or rats, were developed for the study of bacterial and non-bacterial prostatitis.<sup>39,40</sup> C57bl/6 mice develop an autoimmune prostatitis when injected with homogenized mouse prostate, raising the question of whether the inflammatory response in CPPS may be an autoimmune phenomenon.<sup>40</sup> Evidence to support this hypothesis in humans is limited to one small study, and more work is needed before conclusions can be drawn.<sup>41</sup>

Urodynamic studies have suggested a possible neuromuscular origin for CPPS. Abnormal contraction or spasm at the external urethral sphincter may be detectable during voiding, and it has been proposed that the consequent rise in prostatic urethral pressures might provoke prostatic pain (Fig. 63.1).<sup>42–44</sup> Secondary reflux of urine into the prostatic parenchyma might provoke a chemical prostatitis, simulating an inflammatory response. Intraprostatic reflux of urine can be demonstrated in men with inflammatory CPPS, following installation of carbon particles into the bladder.<sup>45</sup> Moreover, prostatic calculi have been shown to be composed of constituents of urine rather than prostatic secretions, implying that such reflux may occur commonly. Functional obstruction at the bladder neck, as proposed by this hypothesis, could explain the subjective reports of flow abnormalities that may be confirmed on uroflowmetry in some patients with CPPS. Neuromuscular abnormalities of this type might be triggered by a range of factors, including urinary or genital infections and other painful processes including surgery and trauma.

**Fig. 63.1:** Possible neuromuscular mechanism for chronic pelvic pain syndrome. Increased tension at the external urethral sphincter (EUS, where pelvic floor meets membranous urethra) causes a rise in prostatic urethral pressure and reflux of urine into prostatic parenchyma, preferentially into peripheral zone (PZ).<sup>42</sup> CZ indicates central zone.

Psychological factors may also be important in the genesis and perpetuation of symptoms in men with CPPS. Studies have demonstrated higher scores than control groups for depression, anxiety, somatization, and hypochondriasis.<sup>46</sup> CPPS has similarities to other regional chronic pain syndromes.<sup>47</sup> It has been proposed that the inflammation detectable in this condition may be neurogenic in origin, caused by release of neuropeptides such as substance P.<sup>49</sup>

## Diagnosis

### ACUTE BACTERIAL PROSTATITIS

The diagnosis of ABP should be suspected in men presenting with symptoms of acute UTI, when perineal or penile pain and obstructive symptoms are present. The finding of a swollen, tender prostate on rectal examination is sufficient to confirm the diagnosis. Imaging by transrectal ultrasound (TRUS) or computed tomographic scan can provide further confirmation. Urine dipstick testing indicates the presence of urinary infection (leukocytes, nitrite, red cells, and protein) and, before antimicrobials are started, urine cultures will usually help identify the responsible organism. Blood cultures may also prove positive. After an episode of ABP, the urinary tract should be investigated by ultrasonography or intravenous urography to exclude a structural predisposing factor for UTI.

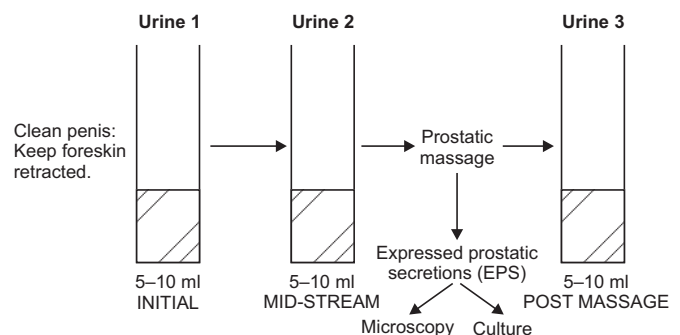

### CHRONIC BACTERIAL PROSTATITIS

The diagnosis of CBP should be suspected in men with recurrent UTI caused by the same organism, when urinary tract imaging does not demonstrate a predisposing cause. TRUS may demonstrate abnormalities of the prostatic parenchyma or the presence of calculi. Prostatic calcification or calculi may also be evident on urography, but these may be also detected in the absence of prostatitis. The 4-glass test may be helpful to confirm CBP (Fig. 63.2). The test should not be performed in the presence of UTI or, ideally, within one week of antibiotic treatment. The aim of the investigation is to examine the EPS, obtainable in approximately 70% of examinations, by microscopy and culture. When EPS are not obtainable, the test relies on quantitative microscopy (for white cells) and culture (colony-forming units) of the urine voided immediately after prostatic massage (urine-3), in comparison with the mid-stream urine (urine-2). In theory, EPS culture should produce a significant growth of the organism responsible for recurrent UTIs, providing confirmation of the presence of a prostatic focus. In practice, even when there is strong clinical suspicion of CBP on the basis of recurrent UTIs, the organism may not be identified by the 4-glass test. The reliability of the test in the diagnosis of CBP has not been determined, and in instances where the test does not provide confirmation of CBP, a therapeutic trial is usually indicated regardless of the results.

### CHRONIC PELVIC PAIN SYNDROME

The diagnosis of CPPS is a clinical one, and because the etiology of the condition is not known, a confirmatory diagnostic test has not been developed. A number of potential investigations have been proposed. McNaughton-Collins conducted a systematic review of candidate diagnostic tests for CPPS, and examined critically those who had been evaluated in control studies.<sup>50</sup> She concluded that no diagnostic test has been identified that is sufficiently validated for use in clinical practice, not even the 4-glass test. This conclusion remains current.

Traditionally, the 4-glass test has been used to investigate suspected prostatitis (see Box 63.1 and Fig. 63.2). The finding of a significant number of white cells in the EPS ( $>1000/\text{mm}^3$  or  $>10/\text{high power field}$ , magnification  $\times 400$ ) has been used

**Fig. 63.2:** The 4-glass test (see Box 63.1).

**Box 63.1** The 4-Glass Test\* (See Fig. 63.2)

Advise patient to hold urine for 2 hours and not to ejaculate for at least 2 days.

No antibiotic for at least 1 week.

**Procedure**

1. Clean end penis with sterile saline or water.
2. Collect first void 5–10 mL (urine-1).
3. Collect mid-stream 5–10 mL (urine-2).
4. Prostatic massage for 1 minute (collect EPS<sup>†</sup>).
5. Clean penis (as for 1).
6. Collect next 5–10 mL and empty bladder (urine-3).

\*EPS indicates expressed prostatic secretions. One drop on slide for immediate microscopy. If sufficient, also send for culture.

Interpretation (See Table 63.1)

Diagnosis	EPS		Urine-3	
	WBC	Culture	WBC	Culture
CBP	+	+	+	+
CPPS, inflammatory	+	-	+	-
CPPS, non-inflammatory	-	-	-	-

<sup>†</sup>>1000 cells/mm<sup>3</sup> or ≥10 cells/hpf (high power field, x400).

<sup>§</sup>WBC in urine-3 minus urine-2 ≥10 cells/hpf.

<sup>\*\*</sup>Quantitative counts; ratio of urine-3/urine-2 ≥10.

\*Modified after Meares & Stamey,<sup>1</sup> Leigh,<sup>22</sup> Schiefer et al.<sup>49</sup> Thin 1997.<sup>63</sup>

as useful confirmation for suspected prostatitis. However, the detection of white cells does not correlate with symptoms, and an asymptomatic inflammatory prostatitis is also known to occur. The significance of asymptomatic prostatic inflammation is not known. If EPS are not obtained, a rise in urinary white cells after prostatic massage has been used as evidence for prostatic inflammation. However, this has not been standardized. Nickel developed a 2-glass technique as a simplified version of the 4-glass test and reported comparable results.<sup>51</sup>

The reliability of the 4-glass test in detecting the presence of prostatic inflammation is not known, because it has not been compared against an independent standard. This means that its positive and negative predictive values are not known. Moreover, the distinction between inflammatory and non-inflammatory CPPS has not been shown to influence clinical management or prognosis. Clinical practice surveys have shown wide variation in use of the 4-glass test in the investigation of CPPS. A survey of urologists in the US revealed that only a small minority request the investigation (80% responded never or rarely).<sup>52</sup> A survey of genitourinary medicine physicians in the UK demonstrated that although the diagnosis of CPPS was frequently made, the 4-glass test was routinely used by only one-third for investigating the condition.<sup>53</sup> Some authors have recommended that the test should be confined to research protocols.<sup>54,55</sup> In the light of findings on cytokine changes that are detectable in both inflammatory and non-inflammatory CPPS, it is debatable whether the 4-glass test provides any useful information in the context of CPPS.

**Differential Diagnosis of CPPS**

In the absence of a reliable confirmatory investigation, CPPS remains a clinical diagnosis that relies on the exclusion of other

**Table 63.3:** Differential Diagnosis of Chronic Pelvic Pain Syndrome (CPPS)

Bladder conditions
Carcinoma in situ or carcinoma <sup>56</sup>
Interstitial cystitis <sup>57</sup>
Bladder outlet obstruction <sup>58</sup>
Bladder irritation by colonic carcinoma or diverticulitis
Seminal vesicle abnormalities
Seminal vesicle calculi <sup>59</sup>
Seminal vesicle cysts (e.g., associated with ipsilateral renal agenesis) <sup>60</sup>
Miscellaneous
Occult inguinal and femoral hernias
Inguinal ligament enthesopathy <sup>61</sup>
Lumbosacral arthropathy
Recurrent genital herpes simplex <sup>62</sup>

potential causes for symptoms. The definition proposed by the NIH recommends exclusion of genital infections including *Chlamydia* and herpes simplex, UTI, bladder neoplasia including carcinoma in situ, urinary tract stone disease, and neurological causes for symptoms.<sup>3</sup> For clinical purposes, a differential diagnosis for CPPS is shown in Table 63.3. In excluding other causes for symptoms, a urine dipstick test should always be performed and significant urine abnormalities, in particular microscopic hematuria, should not be attributed to CPPS. The presence of irritant-type voiding symptoms should be investigated by cystoscopy to exclude bladder carcinoma, carcinoma in situ, and interstitial cystitis.<sup>56,57</sup> Obstructive urinary symptoms with a flattened trace on uroflowmetry should be investigated by cystoscopy to exclude bladder outlet obstruction and urethral stricture.<sup>58</sup> Although TRUS has been recommended as a diagnostic test for CPPS, changes in the prostatic parenchyma that are frequently identified are relatively non-specific and the test cannot be used to confirm the diagnosis.<sup>50</sup> TRUS may identify prostatic cysts that may be amenable to drainage.<sup>63</sup> Urinary tract imaging, for instance by ultrasonography, will rarely detect a relevant structural abnormality. The presence of a significant residual bladder volume on ultrasound should lead to further investigation to exclude bladder outlet obstruction.<sup>58</sup> If renal agenesis is identified, this should raise the possibility of ipsilateral seminal vesicle abnormalities, including cystic changes, which can predispose to recurrent pelvic pain and may be amenable to drainage or excision.<sup>60</sup>

**Management****ACUTE BACTERIAL PROSTATITIS**

Patients with ABP require urgent treatment with an antibiotic regimen that is likely to cover uropathogens while waiting for culture and sensitivity results. Rest and adequate hydration should be recommended and analgesia prescribed as necessary. Although controlled trials are not available to guide antibiotic

selection or duration of treatment, penetration of antibiotics into the acutely inflamed prostate is likely to be good, and in mild episodes, oral treatment with co-amoxiclav (amoxicillin + clavulanic acid) or a quinolone such as ciprofloxacin may be sufficient. The antibiotic may need to be changed in the light of culture and sensitivity results. Patients with severe systemic features and those whose condition does not respond rapidly to oral treatment, may need admission to hospital for intravenous antibiotics. In general, a prolonged course of treatment is recommended, for instance 4 weeks, with the aim of reducing the risk of subsequent CBP.<sup>11,18</sup>

Acute retention of urine is an occasional complication of ABP, and should be managed by suprapubic catheterization. Urethral catheterization should be avoided because of the risk of damage to the swollen prostate. Prostatic abscess is a rare but serious complication of ABP, requiring drainage by transurethral or perineal routes.<sup>19</sup>

### CHRONIC BACTERIAL PROSTATITIS

In the pre-quinolone era, CBP had a reputation for persistence despite prolonged courses of antibiotics. Antibiotic penetration across the prostate-blood barrier was thought to be a factor. Observational studies suggested eradication rates of only 30–40% for co-trimoxazole, after 3-month treatment.<sup>64</sup> The sulfonamide component of co-trimoxazole does not penetrate well into the prostate and trimethoprim may, therefore, be equally effective. The advent of quinolone antibiotics revolutionized the treatment of CBP. However, only a few controlled trials of oral antibiotic treatment of CBP have been published. In 5 studies evaluating quinolones in CBP involving a total of 121 patients, the reported non-recurrence rates were 82% at one month after treatment, and 64% at 6 months after treatment (using courses of 2–7 weeks duration).<sup>65–68</sup> These and observational reports suggest that initial therapy for CBP with 4 weeks of a quinolone is reasonable, assuming a sensitive organism. Ciprofloxacin, 500 mg twice daily or ofloxacin 200–400 mg twice daily is a suitable choice. CBP that recurs despite treatment is fortunately rare, and management is difficult. Options include using longer courses of quinolone, such as 5 months, or a combined medical and surgical approach.<sup>69,70</sup>

### CHRONIC PELVIC PAIN SYNDROME

The management of CPPS is generally unsatisfactory, in that no reliably effective treatments have been identified.<sup>12,65</sup> Numerous candidate treatments have been reported, mostly in uncontrolled studies. Caution is required in interpreting the results of such studies, because benefit in the placebo arms of blinded, controlled trials has been as high as 30%.<sup>71</sup> Therefore, response rates at this level in uncontrolled studies may not indicate a genuine treatment effect.

The NIH chronic prostatitis symptom index is a widely adopted questionnaire about symptoms which can be useful in monitoring symptom severity and impact over time and after trials of treatment.<sup>7</sup>

\*Adapted from Luzzi G.<sup>12</sup>

A range of candidate treatments that have been proposed or evaluated for CPPS is shown in Table 63.4. In her systematic review for the Cochrane collaboration, McNaughton-Collins examined published randomized or controlled trials and identified 14 that met the inclusion criteria.<sup>50</sup> Quantitative analysis was prevented by variations in study design and interventions used. This critical examination of reported treatments for CPPS concluded that no treatment approach is currently supported by good evidence. Despite the lack of supporting evidence for benefit, antibiotics are frequently used as first-line treatment for CPPS. If antibiotics are used for CPPS, it is logical to select agents with broad-spectrum activity and good prostatic penetration, such as doxycycline, ofloxacin, and erythromycin. A proportion of patients seem to benefit, and this may relate to the non-antibiotic properties of some of these agents. For instance, tetracyclines are known to have anti-inflammatory effects, and quinolones may influence cytokine pathways.<sup>89</sup> However, the evidence does not support prolonged use of antibiotic treatment for CPPS.

Early small, controlled, and observational studies of alpha blockers in CPPS showed variable results, with apparent benefit in a proportion of men.<sup>50,78,79</sup> Alpha blockers may act in CPPS by relaxing smooth muscle at the bladder outlet, and may therefore be particularly helpful in men reporting flow abnormalities and prominent urinary symptoms including frequency and nocturia. Alfuzosin and tamsulosin have been considered to be reasonable choices to try in men with persistent symptoms. Unfortunately, more recent controlled studies of alpha blockers in CPPS have not confirmed clinical benefit and their role in the management of CPPS has become uncertain.<sup>90,91</sup>

Transurethral microwave thermotherapy and treatment with allopurinol were reported to be effective in small, controlled trials, but have not been widely adopted.<sup>83,84</sup> Other treatments reported to help some patients in observational studies or anecdotally include pollen extract, repetitive prostatic massage, acupuncture, and oral corticosteroid. However, the available evidence does not justify recommending their use.<sup>85,92</sup>

Finasteride is a 5 alpha-reductase inhibitor that reduces prostate size; 5 mg daily was reported to improve prostatitis symptom scores in comparison with placebo in 41 men with inflammatory CPPS, after a 12-month treatment period. However, pain scores did not show significant reduction.<sup>87</sup> Quercetin, a naturally occurring bioflavonoid with known anti-inflammatory and anti-oxidant properties, was reported to produce a significant reduction in NIH symptom scores, in a coformulation with bromelain and papain. After one month, two-thirds of men reported benefit in comparison with 20% in the placebo group.<sup>88</sup> This was a well-designed study, but long-term outcome data are not available, and the results need to be confirmed in a larger trial before conclusions can be drawn.

Pain management approaches have been underevaluated in CPPS. Treatments that are well-established in other chronic pain syndromes include low-dose tricyclic antidepressants and the anticonvulsant gabapentin.<sup>81</sup> These are occasionally used in CPPS and deserve systematic evaluation, as do psychological approaches including cognitive behavioral therapy.

In practice, many patients with mild symptoms of CPPS respond to reassurance and an explanation of why their symptoms arise, using diagrams and a leaflet to take away. Simple measures that may be helpful include regular ejaculation and hot sitz baths. In individual cases, avoidance of provoking physical or dietary factors may be appropriate; these are highly variable and may include cycling, caffeine, and alcohol. The response to simple analgesics and non-steroidal, anti-inflammatory drugs is often disappointing. A 2- to 4-week course of doxycycline, ofloxacin, or erythromycin may be tried. Patients with severe persistent symptoms present a difficult management problem that may seem intractable, with associated psychological factors. A trial of alpha blocker or low-dose tricyclic antidepressant may be considered. Coexistent depression should be evaluated and treated appropriately, and referral for specialist assessment of this may be justified. Patients with significant chronic symptoms may derive support from sharing their experience with other prostatitis/CPPS sufferers via the internet.

## Prognosis of Chronic Pelvic Pain Syndrome

Although effective treatment has not been identified, patients can be advised that there is a reasonable likelihood that they will experience amelioration of symptoms over time. In recently diagnosed CPPS, most men experience some improvement in symptoms over the subsequent 6 months.<sup>93</sup> In the largest natural history study of men with CPPS, one-third showed moderate or marked improvement over 2 years.<sup>94</sup>

## Isolated Testicular Pain

Although testicular pain can be a feature of CPPS, chronic pain confined to one or both testicles is usually regarded as a distinct entity and there may be some practical value in considering isolated testicular pain separately. Chronic testicular pain, defined as pain present for more than 3 months, is not a rare condition, yet surprisingly few series have been reported in the medical literature. The range of causes was considered in a series of 43 patients (Table 63.5): at least quarter had no identifiable cause.<sup>95,96</sup> This proportion is likely to be higher in non-surgical settings. The relationship between acute epididymitis and subsequent chronic testicular pain has not been studied systematically and in this series, 35% of men with chronic testicular pain had a history of previous epididymitis. Chronic pain may also follow vasectomy. Chronic pain lasting more than 3 months has been reported in up to 5% of men after this procedure.<sup>97</sup>

The pathogenesis of chronic testicular pain is not understood. Histological examination of epididymectomy and orchidectomy specimens following surgery for chronic pain reveals abnormalities in only a small minority. These are mostly chronic, non-specific, inflammatory changes, and testicular tubular atrophy that may be an incidental finding.<sup>96</sup> The features that suggest a regional chronic pain syndrome include the lack of abnormal physical findings or abnormalities on investigation, and a history of multiple, unsuccessful treatments. As in other chronic pain syndromes, the condition may follow an initiating or trigger event, such as an infection, a surgical procedure, or an episode of trauma. Subsequently, factors that promote the maintenance of pain include biological factors such as nerve damage, upregulation of pain circuits, and psychological factors including personality type and depression.

In the management of chronic testicular pain, there are no controlled trials to assist decision making. Conventional

**Table 63.5:** Causes of Isolated Chronic Testicular Pain in a Series of 43 Patients<sup>95</sup>

	(%)

<sup>a</sup>Varicocele, hydrocele, and testis tumor.

analgesics and anti-inflammatory agents are often unhelpful. As for other chronic pain syndromes, a trial of low-dose tricyclic antidepressant, such as amitriptyline, may be considered. Spermatic cord block using a mixture of local anesthetic and steroid may relieve pain, but the effect is usually transient.<sup>98</sup> The procedure can help identify the subgroup of men who are likely to respond to more destructive approaches, such as nerve stripping or microsurgical denervation of the spermatic cord.<sup>97–99</sup> However these specialized techniques are not widely available, and are associated with some risk of testicular atrophy if the testicular artery is damaged. In postvasectomy pain, reversal of vasectomy (vasovasostomy) may be considered but its effectiveness is unclear from the literature, and men may be reluctant to undergo the procedure.<sup>96</sup> Epididymectomy or orchidectomy is sometimes considered for intractable testicular pain. However, it has been reported that epididymectomy is often ineffective and should be avoided.<sup>96</sup> Orchidectomy may be considered as a last resort, but even this may not abolish the pain and some authors advise avoidance<sup>100</sup>; this might possibly be explained in some cases by misdiagnosis, in men who report testicular pain in the context of CPPS. The anticonvulsant gabapentin, which has been reported to help some patients with chronic testicular pain in a small observational series,<sup>81</sup> and psychological approaches including cognitive behavioral therapy, deserve systematic evaluation.

## Conclusion

Chronic genital and pelvic pain is a relatively common condition of otherwise healthy adult males, and is capable of substantial morbidity. It is useful to subdivide the major syndromes related to chronic genital and pelvic pain in men into ABP and CBP, CPPS, and isolated testicular pain syndrome. While symptoms of CPPS are typically highly variable and usually run a chronic remitting and relapsing course, the cause of CPPS remains unknown despite 20 years of investigation. A central role for the inflammatory response in this condition is supported by the finding of elevations in certain pro-inflammatory and anti-inflammatory cytokines. Urodynamic studies have suggested a possible neuromuscular origin for CPPS. Psychological factors may also be important in the genesis and perpetuation of symptoms in men with CPPS. In the absence of a reliable confirmatory investigation, CPPS remains a clinical diagnosis that relies on the exclusion of other potential causes for symptoms. The management of CPPS is generally unsatisfactory, in that no reliably effective treatments have been identified; however, symptoms improve in a substantial proportion of men over a timescale of 6 months to 2 years.

ABP is most often an uncommon complication of UTI. The finding of a swollen, tender prostate on rectal examination is sufficient to confirm the diagnosis, and patients require urgent treatment with an antibiotic regimen that is likely to cover uropathogens.

In CBP, a nidus of infection becomes established in the prostate and causes relapsing illness. This may follow an acute UTI or episode of ABP, after failure of antibiotic treatment to clear the prostate of infection. The diagnosis of CBP should be suspected

in men with recurrent UTI caused by the same organism, when urinary tract imaging does not demonstrate a predisposing cause. The advent of quinolone antibiotics revolutionized the treatment of CBP and recurrence after treatment is fortunately uncommon.

Although testicular pain can be a feature of CPPS, chronic pain confined to one or both testicles is usually regarded as a distinct entity. The pathogenesis of chronic testicular pain is poorly understood and the management remains unsatisfactory.

## Ocular Manifestations of Sexually Transmitted Infections

Jyotirmay Biswas • Parthopratiim Dutta Majumder  
• Sudharshan S.

### Introduction

The World Health Organization estimates that 480 million new cases of sexually transmitted diseases (STDs) have occurred throughout the world in the year 2005 in men and women aged 15–49 years.<sup>1</sup> Despite stepped-up public awareness campaigns in recent years regarding the hazards of unprotected sexual intercourse, sexually transmitted diseases continue to exact a troubling toll on our society. Many of these conditions commonly affect the eye, and thus pose a critical concern for primary care. The ophthalmologist can even be the initial clinician who identifies the systemic condition, as patients may often seek advice when vision is impaired. This chapter provides an overview of ocular lesions in various sexually transmitted infections. Common sexually transmitted infections, which may cause ophthalmic lesions, are enumerated in Table 64.1.

### Syphilis

Syphilis is a systemic infection caused by a spirochete, *Treponema pallidum*, which can produce multiple ocular inflammatory and structural changes. The first clear clinical description of syphilis was published during the Renaissance, when the disease spread across Europe. At that time syphilis was termed as the “great pox” to distinguish it from small pox. The ocular manifestations of syphilis, singly and as a coinfection with HIV, are summarized below.

**Table 64.1:** Common Sexually Transmitted Diseases Causing Ocular Lesions

- |      |  |
|------|--|
| I.   | Syphilis                               |
| II.  | <i>Neisseria gonorrhoeae</i> infection |
| III. | Chlamydia trachomatis infection        |
| IV.  | Genital herpes                         |
| V.   | Crab louse infestation                 |
| VI.  | Human immunodeficiency virus infection |

### OCULAR LESIONS IN THE VARIOUS CLINICAL STAGES OF SYPHILIS

#### Primary Syphilis

The first clinical sign of syphilis is the chancre, which generally occurs in the area of invasion by *Treponema pallidum* usually 3 weeks after exposure. Extragenital chancres may be seen on the lip, tongue, tonsil, nipple, finger, and anus. Primary lesions are rarely found on the eyelids or conjunctiva.<sup>2</sup> Other ocular signs in the primary stage include conjunctivitis and blepharitis.

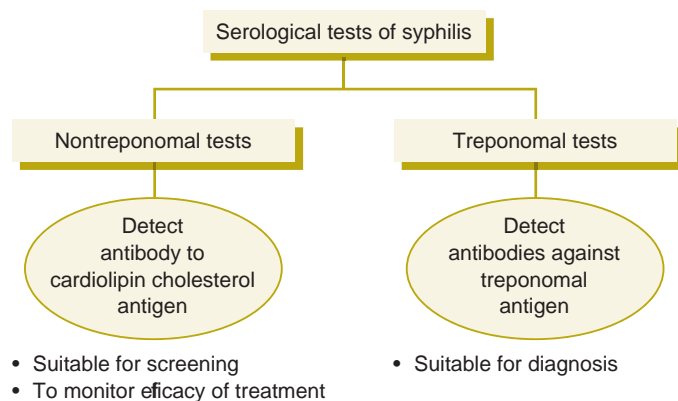

#### Secondary Syphilis

Three weeks to 6 months after the primary infection with *Treponema pallidum*, hematogenous dissemination of the organism may be associated with the signs and symptoms of secondary syphilis. Ocular involvement is strongly suggestive of the involvement of the central nervous system (CNS) and may be considered as synonymous with neurosyphilis.<sup>3–5</sup> Secondary syphilis is characterized by a painless maculopapular skin rash, and although the face is spared, sometimes the eyelids may be affected. Hair follicle involvement may lead to temporary loss of the outer half of the eyebrows or eyelashes and patchy loss of hair on the face and scalp. Anterior uveitis, manifesting as a mild acute iritis is the most common ocular manifestation of this stage and occurs in about 5% of untreated cases,<sup>6</sup> but seldom before the sixth month of infection. The other eye is affected in nearly one-half of the patients. Diffuse and nodular scleritis (Figs. 64.1 and 64.2) can manifest in secondary syphilis. Choroiditis with vitritis can also develop during the late secondary stage and lead to focal chorioretinal atrophy. Central nervous system involvement with its ocular manifestations may be found in about one-fourth of the patients with secondary syphilis (see below).<sup>3,7,8</sup>

#### Tertiary Syphilis

About one-third of the patients develop the clinical signs of obliterative endarteritis in late syphilis, usually many years after the

**Fig. 64.1:** Serological tests used for diagnosis of syphilis.

**Fig. 64.2:** Diffuse scleritis in syphilis.

onset of disease. Ocular signs have been noted in approximately 10% of patients with tertiary syphilis. Pupillary abnormalities are among the most common ocular manifestations (Table 64.2).<sup>9,10</sup>

**Gummas:** Gummas are necrotic, granulomatous lesions produced by focal obliterative endarteritis. They may involve any organ including the eye. In the eye, gummatous lesions are commonly found in the lacrimal structures, orbit, and optic nerves. Gummas on the cornea and sclera have been reported.<sup>11–14</sup>

**Cardiovascular syphilis and the eye:** Eye involvement in patients with cardiovascular syphilis occurs as a result of syphilitic vasculitis. The common ocular features of syphilitic vasculitis include scleritis, chronic iridocyclitis, choroiditis, and retinal vasculitis with periarteriolar sheathing.

## NEURO-OPHTHALMIC FEATURES

### Optic Nerve

The optic nerve is affected in a substantial proportion of patients with secondary syphilis or tertiary syphilis.

- Optic perineuritis is an inflammation of the meningeal sheaths of the optic nerve that produces a mild swelling of the optic disc but does not adversely affect visual acuity, color vision, or the visual field.<sup>15</sup>

**Table 64.2:** Structure-wise Involvement of the Eye in Syphilis

Ocular structure	Type of lesion/ involvement
<b>Eyelid</b>	Chancre Gumma Tarsitis Ulcerative blepharitis
<b>Conjunctiva</b>	Chancre Granuloma Tarsitis
<b>Orbit</b>	Periostitis Gumma (extraocular muscle, lacrimal gland or within orbit)
<b>Cornea</b>	Interstitial keratitis Ulcers Deep punctate keratitis Keratitis profunda Keratitis punctate profunda Keratitis pustuliformis profunda Keratitis linearis migrans
<b>Sclera</b>	Episcleritis Scleritis (nodular or diffuse; anterior or posterior) Gumma
<b>Iris and ciliary body</b>	Roseola Papules Gumma
<b>Pupil</b>	Light- near dissociation (A-R pupil)
<b>Lens</b>	Capsular rupture and necrotizing cortical inflammation Traumatic dislocation
<b>Glaucoma</b>	Secondary to uveitis (late manifestation)
<b>Optic nerve</b>	Perineuritis Anterior optic neuritis Retrobulbar neuritis Neuroretinitis Papilledema Optic atrophy
<b>Motility Dysfunctions</b>	Oculomotor, abducens, trochlear associated paresis Basilar meningitis Periodic alternating nystagmus
<b>Retina and vitreous</b>	Chorioretinitis—pseudoretinitis pigmentosa, salt and pepper fundus Perivasculitis Central retinal artery/vein occlusion Cystoid macular edema Vitreitis Exudative retinal detachment

- Anterior optic neuritis usually occurs in the late secondary stage of syphilis. It may develop during the course of syphilitic meningitis, or it may occur as an isolated phenomenon. Visual loss is rapid and usually associated with the development of visual field defects (Fig. 64.3).<sup>16</sup>
- Neuroretinitis is a condition in which anterior optic neuritis is associated with the deposition of lipids (hard exudates) in the papillomacular region (Fig. 64.4).<sup>17,18</sup>

**Fig. 64.3:** Optic neuritis with retinal hemorrhages in syphilis.

**Fig. 64.4:** Neuroretinitis with optic disc pallor.

- Retrobulbar optic neuritis may occur in patients with syphilitic retinitis, syphilitic meningitis, or syphilitic periosteitis that affects the orbit.<sup>19</sup>
- Papilledema may develop in patients with secondary syphilis as a result of increased intracranial pressure due to meningitis.<sup>20,21</sup>
- Optic atrophy appears as a sharply defined, pale optic disc with narrowing of retinal arterioles. About 5% of the patients with neurosyphilis develop optic atrophy.<sup>3,22</sup> Sometimes the presence of optic atrophy may be the sole manifestation. Involvement of the other eye usually occurs after months to years. Optic atrophy probably occurs as a result of endarteritis of the intramural small vessels with lymphocytic infiltration of pial sheath of the optic nerve.<sup>11</sup>

## Cranial Nerves

Cranial nerve palsies are most often caused by syphilitic basilar meningitis.<sup>2</sup> Other causes include gummas along the nerves, brainstem infarcts, and periosteitis of the superior orbital fissure. Syphilitic vascular changes can produce aneurysms and even subdural hematomas with cranial nerve manifestations. Trigeminal neuralgia with severe pain can occur secondary to syphilitic meningitis or osteitis of the periosteal bone. Lagophthalmos can occur from nuclear or supranuclear degeneration. Cases of vestibular nystagmus and periodic alternating nystagmus have been reported.<sup>23</sup>

## Visual Field Defects

Various types of visual field defects can occur in ocular syphilis depending upon the involvement of the visual pathway (Table 64.3).<sup>24</sup>

### Pupil

The classical pupillary finding in syphilis, the Argyll Robertson pupil, is usually seen in tertiary syphilis. The pupils are unequal, irregular, and profoundly miotic. Pupillary constriction in response to light is weak or absent but is normal or exaggerated in response to accommodation. The basal miosis is unaffected by exposure to dark and painful stimuli. The dissociated response is due to interruption of intranuclear neurons connecting the Edinger–Westphal nucleus with other pretectal nuclei.

Other causes of Argyll Robertson pupil include diabetes mellitus, alcoholism, encephalitis, and multiple sclerosis.<sup>25</sup>

### Interstitial Keratitis (IK)
